DUMMY ENDOGENOUS VARIABLES IN A SIMULTANEOUS EQUATION SYSTEM

BY JAMES J. HECKMAN

This paper considers a class of simultaneous equation models with both discrete and continuous random variables based on normally distributed latent random variables. The model set forth here contains the classical simultaneous equation model for continuous endogenous variables and more recent models for discrete endogenous variables as special cases of a more general model. Conditions for the existence of the model are developed. Identification criteria are provided and consistent estimators are proposed. The model set forth here is contrasted with the models of Goodman and Nerlove and Press.

This paper considers the formulation and estimation of simultaneous equation models with both discrete and continuous endogenous variables. The statistical model proposed here is sufficiently rich to encompass the classical simultaneous equation model for continuous endogenous variables and more recent models for purely discrete endogenous variables as special cases of a more general model.

Interest in discrete data has been fueled by a rapid growth in the availability of microeconomic data sets coupled with a growing awareness of the importance of discrete choice models for the analysis of microeconomic problems (see McFadden [20]). To date, the only available statistical models for the analysis of discrete endogenous variables have been developed for the purely discrete case. The log-linear or logistic model of Goodman [7] as expanded by Haberman [10] and Nerlove and Press [22] is one such model that has been widely used. The multivariate probit model of Ashford and Sowden [3], Amemiya [2], and Zellner and Lee [30] is another widely used model. This paper expands the multivariate probit structure to accommodate continuous endogenous variables. Alternatively, the model presented here expands the classical simultaneous equation theory to encompass multivariate probit models.

The models developed below rely critically on the notion that discrete endogenous variables are generated by continuous latent variables crossing thresholds. Such models have an honored place in the history of statistics and were first advanced by Pearson [25]. The theory of biserial and tetrachoric correlation is based on this idea. (See Kendall and Stuart [16, Vol. II], Lord and Novick [18, Chs. 16–20]). It is argued in this paper that this class of statistical models provides a natural framework for generating simultaneous equation models with both discrete and continuous random variables.

1 This research was supported by NSF and ASPER Department of Labor grants to the National Bureau of Economic Research. Takeshi Amemiya, A. Araujo, R. Bahadur, Linda Edwards, Zvi Griliches, Tom MacCurdy, Marc Nerlove, Randy Olsen, Donald Sant, J. Scheinkman, Peter Schmidt, G. Sedlacek, and Arnold Zellner all made valuable comments on drafts of this paper. I assume all responsibility for any remaining errors. The first draft of this paper appeared under the same title as an unpublished NBER paper in April, 1973. A second draft was circulated under a different title and presented at the World Econometric Society Meetings at Toronto, 1975.
In contrast, the framework of Goodman, while convenient for formulating descriptive models for discrete data, offers a much less natural apparatus for analyzing econometric structural equation models. This is so primarily because the simultaneous equation model is inherently an unconditional representation of behavioral equations while the model of Goodman is designed to facilitate the analysis of conditional representations and does not lend itself to the unconditional formulations required in simultaneous equation theory.

This paper is in four parts. In Section 1 general models are discussed. Dummy endogenous variables are introduced in two distinct roles: (1) as proxies for unobserved latent variables, and (2) as direct shifters of behavioral equations. Five models incorporating such dummy variables are discussed. Section 2, also the longest section, presents a complete analysis of the most novel and most general of the five models presented in Section 1. This is a model with both continuous and discrete endogenous variables. The issues of identification and estimation are discussed together by proving the existence of consistent estimators. Maximum likelihood estimators and alternative estimators are discussed. In Section 3, a brief discussion of a multivariate probit model with structural shift is presented. Section 4 presents a comparison between the models developed in this paper and the models of Goodman and Nerlove and Press.

1. A GENERAL MODEL FOR THE TWO EQUATION CASE

Since few new issues arise in the multiple equation case, for expositional simplicity the bulk of the analysis in this paper is conducted for a two equation system. All of the models considered in this paper can be subsumed as special cases of the following pair of simultaneous equations for continuous latent random variables $y_{1i}^*$ and $y_{2i}^*$,

(1a) \[ y_{1i}^* = X_1 \alpha_1 + d_1 \beta_1 + y_{2i}^* \gamma_1 + U_{1i} \]

(1b) \[ y_{2i}^* = X_2 \alpha_2 + d_2 \beta_2 + y_{1i}^* \gamma_2 + U_{2i} \]

where dummy variable $d_i$ is defined by

(1c) \[ d_i = 1 \quad \text{iff} \quad y_{2i}^* > 0, \]

\[ d_i = 0 \quad \text{otherwise}, \]

and

$$E(U_{1i}) = 0, \quad E(U_{2i}^2) = \sigma_{\beta}, \quad E(U_{1i}U_{2i}) = \sigma_{12}, \quad j = 1, 2; i = 1, \ldots, I. \]

$$E(U_{1i}U_{j'i'}) = 0, \quad \text{for} \quad j, j' = 1, 2; i \neq i'. \]

"$X_{1i}$" and "$X_{2i}$" are, respectively, $1 \times K_1$ and $1 \times K_2$ row vectors of bounded exogenous variables. The joint density of continuous random variables $U_{1i}, U_{2i}$ is $g(U_{1i}, U_{2i})$ which is assumed to be a bivariate normal density in the analysis of Sections 2 and 3. In order to focus attention on the essential features of the

\[ 2 \text{ Clearly, a second dummy variable could be defined as arising from } y_{1i}^* \text{ crossing a threshold. Note, too, that the choice of the zero threshold is an arbitrary normalization.} \]
argument, the conventional assumptions of classical simultaneous equation theory are maintained. In particular, it is assumed that equations (1a) and (1b) are identified if $\beta_1 = \beta_2 = 0$ and both $y_{1i}^*$ and $y_{2i}^*$ are observed for each of the $I$ observations. In this special case, which conforms to the classical simultaneous equation model, standard methods are available to estimate all of the parameters of the structure.

The full model of equations (1a)–(1c) is sufficiently novel to require some discussion. First, note that the model is cast in terms of latent variables $y_{1i}^*$ and $y_{2i}^*$ which may or may not be directly observed. Even if $y_{2i}^*$ is never observed, the event $y_{2i}^* > 0$ is observed and its occurrence is recorded by setting a dummy variable, $d_i$, equal to one. If $y_{2i}^* < 0$, the dummy variable assumes the value zero. Second, note that if $y_{2i}^* > 0$, structural equations (1a) and (1b) are shifted by an amount $\beta_1$ and $\beta_2$ respectively.

To fix ideas, several plausible economic models are discussed that may be described by equation system (1a)–(1c). First, suppose that both $y_{1i}^*$ and $y_{2i}^*$ are observed outcomes of a market at time $i$, say quantity and price. Equation (1a) is the demand curve while equation (1b) is the supply curve. If the price exceeds some threshold (zero in inequality (1c), but this can be readily amended to be any positive constant), the government takes certain actions that shift both the supply curve and the demand curve, say a subsidy to consumers and a per unit subsidy to producers. These actions shift the demand curve and the supply curve by the amount $\beta_1$ and $\beta_2$, respectively.

As another example, consider a model of the effect of laws on the status of nonwhites. Let $y_{1i}^*$ be the measured income of nonwhites in state $i$ while $y_{2i}^*$ is an unmeasured variable that reflects the state’s population sentiment toward nonwhites. If sentiment for nonwhites is sufficiently favorable ($y_{2i}^* > 0$), the state may enact antidiscrimination legislation and the presence of such legislation in state $i$, a variable that can be measured, is denoted by a dummy variable $d_i = 1$. In the income equation (1a), both the presence of a law and the population sentiment towards nonwhites is assumed to affect the measured income of nonwhites. The first effect is assumed to operate discretely while the second effect is assumed to operate in a more continuous fashion. An important question for the analysis of policy is to determine whether or not measured effects of legislation are due to genuine consequences of legislation ($\beta_1 \neq 0$) or to the spurious effect that the presence of legislation favorable to nonwhites merely proxies the presence of pro-black sentiment that would lead to higher status for nonwhites in any event ($\gamma_1 \neq 0$). In Section 2, methods for consistently estimating the separate effects ($\beta_1$ and $\gamma_1$) are presented. This example is valuable because it illustrates two conceptually distinct roles for dummy variables: (1) as indicators of latent variables that cross thresholds and (2) as direct shifters of behavioral functions. These two roles must be carefully distinguished in the ensuing analysis.

3 For reasons that become clearer in the analysis of Section 2, identification is assumed to be secured through exclusion restrictions or through restrictions on reduced forms for covariance parameters that are estimable.

4 Note that even if sentiment were measured (i.e., $y_{2i}^*$ were known), least squares estimators of equation (1a) are inconsistent because of the correlation of $d_i$ and $y_{2i}^*$ with $U_{1i}$.
The model of equations (1a)–(1c) subsumes a wide variety of interesting econometric models. These special cases are briefly discussed in turn.

**CASE 1—The Classical Simultaneous Equation Model**: This model arises when $y_{1i}^*$ and $y_{2i}^*$ are observed, and there is no structural shift in the equations ($\beta_1 = \beta_2 = 0$).

**CASE 2—The Classical Simultaneous Equation Model with Structural Shift**: This model is the same as that of Case 1 except that structural shift is permitted in each equation. It will be shown below that certain restrictions must be imposed on the model in order to generate a sensible statistical structure for this case.

**CASE 3—The Multivariate Probit Model**: This model arises when $y_{1i}^*$ and $y_{2i}^*$ are not observed but the events $y_{1i}^* \leq 0$ and $y_{2i}^* \leq 0$ are observed (i.e., one knows whether or not the latent variables have crossed a threshold). The notation of equations (1a)–(1c) must be altered to accommodate two dummy variables but that modification is obvious. No structural shift is permitted ($\beta_1 = \beta_2 = 0$). This is the model of Ashford and Sowden [3], Amemiya [2], and Zellner and Lee [30].

**CASE 4—The Multivariate Probit Model with Structural Shift**: This model is the same as that of Case 3 except that structural shift is permitted ($\beta_1, \beta_2 \neq 0$).

**CASE 5—The Hybrid Model**: This model arises when $y_{1i}^*$ is observed and $y_{2i}^*$ is not, but the event $y_{2i}^* \geq 0$ is observed. No structural shift is permitted ($\beta_1 = \beta_2 = 0$).

**CASE 6—The Hybrid Model with Structural Shift**: This model is the same as that of Case 5 except that structural shifts in the equations are permitted.

The hybrid models of Cases 5 and 6 are the most novel and general. Accordingly, these cases receive the greatest attention in the ensuing analysis. Models 2 and 4 are also new but since the analysis of these models follows directly from the analysis of the hybrid model they receive less attention in this paper. Case 4 is briefly discussed in Section 3 while Case 2 is never explicitly developed.

2. THE HYBRID MODEL WITH STRUCTURAL SHIFT

In this section, a model with one observed continuous random variable, and one latent random variable is analyzed for the general case of structural shift in the equations. The argument proceeds in the following steps. First, a condition for the existence of a meaningful statistical model is derived. Second, consistent estimators of identified parameters are presented. Third, maximum likelihood estimators are discussed. Finally, some alternative estimators are presented and discussed.
To facilitate the discussion, equations (1a) and (1b) may be written in semi-reduced form as
\[
y_{1i} = X_{1i}\pi_{1i} + X_{2i}\pi_{12} + d_i\pi_{13} + V_{1i},
\]
\[
y_{2i}^* = X_{1i}\pi_{21} + X_{2i}\pi_{22} + d_i\pi_{23} + V_{2i},
\]
\[
d_i = 1 \quad \text{iff} \quad y_{2i}^* \geq 0,
\]
\[
= 0 \quad \text{otherwise},
\]
where
\[
\pi_{11} = \frac{\alpha_1}{1-\gamma_1\gamma_2}, \quad \pi_{21} = \frac{\alpha_1\gamma_2}{1-\gamma_1\gamma_2}, \quad \pi_{12} = \frac{\alpha_2\gamma_1}{1-\gamma_1\gamma_2}, \quad \pi_{22} = \frac{\alpha_2}{1-\gamma_1\gamma_2},
\]
\[
\pi_{13} = \frac{\beta_1 + \gamma_1\beta_2}{1-\gamma_1\gamma_2}, \quad \pi_{23} = \frac{\gamma_2\beta_1 + \beta_2}{1-\gamma_1\gamma_2}, \quad V_{1i} = \frac{U_{1i} + \gamma_1 U_{2i}}{1-\gamma_1\gamma_2},
\]
\[
V_{2i} = \frac{\gamma_2 U_{1i} + U_{2i}}{1-\gamma_1\gamma_2}.
\]

In the ensuing analysis it is assumed that exogenous variables included in both \(X_{1i}\) and \(X_{2i}\) are allocated to either \(X_{1i}\) or \(X_{2i}\), but not both. The absence of an asterisk on \(y_{1i}\) denotes that this variable is observed. "\(y_{2i}^*\)" is not observed. Random variables \(U_{1i}\) and \(U_{2i}\) are assumed to be bivariate normal random variables. Accordingly, the joint distribution of \(V_{1i}, V_{2i}, h(V_{1i}, V_{2i})\), is a bivariate normal density fully characterized by the following assumptions:
\[
E(V_{1i}) = 0, \quad E(V_{2i}) = 0,
\]
\[
E(V_{1i}^2) = \omega_{11}, \quad E(V_{1i}V_{2i}) = \omega_{12}, \quad E(V_{2i}^2) = \omega_{22},
\]

To obtain the true reduced form equations, assume that the conditional probability that \(d_i\) is unity given \(X_{1i}\) and \(X_{2i}\) exists, and denote this probability by \(P_i\). Then the true reduced forms may be written
\[
y_{1i} = X_{1i}\pi_{11} + X_{2i}\pi_{12} + P_i\pi_{13} + V_{1i} + (d_i - P_i)\pi_{13},
\]
\[
y_{2i}^* = X_{1i}\pi_{21} + X_{2i}\pi_{22} + P_i\pi_{23} + V_{2i} + (d_i - P_i)\pi_{23},
\]
\[
d_i = 1 \quad \text{iff} \quad y_{2i}^* \geq 0,
\]
\[
d_i = 0 \quad \text{otherwise}.
\]

The error term in each equation consists of the sum of continuous and discrete random variables that are correlated. The errors have zero conditional mean but if \(P_i\) is a nontrivial function of \(X_{1i}, X_{2i}\), heteroscedasticity is present in the errors.

(i) Conditions for Existence of the Model\(^5\)

The first order of business is to determine whether or not the model of equations (1a)–(1b) as represented in reduced form by equations (3a)–(3b)

\(^5\) I am grateful to Peter Schmidt for correcting an important error in the argument of this section in a previous draft.
makes sense. Without imposing a further restriction, it does not. The restriction required is precisely the restriction implicitly assumed in writing equations (3a) and (3b), i.e., the restriction that permits one to define a unique probability statement for the events \( d_i = 1 \) and \( d_i = 0 \) so that \( P_i \) in fact exists. A necessary and sufficient condition for this to be so is that \( \pi_{23} = 0 \), i.e., that the probability of the event \( d_i = 1 \) is not a determinant of the event. Equivalently, this assumption can be written as the requirement that \( \gamma_2 \beta_1 + \beta_2 = 0 \). This condition is critical to the analysis and thus deserves some discussion. The argument supporting this assumption is summarized in the following proposition.

**Proposition:** A necessary and sufficient condition for the model of equations (1a)–(1c) or (3a)–(3c) to be defined is that \( \pi_{23} = 0 = \gamma_2 \beta_1 + \beta_2 \). This assumption is termed the principal assumption.

**Proof:** Sufficiency is obvious. Thus, only necessary conditions are discussed. Denote the joint density of \( V_{2i}, d_i \) by \( t(V_{2i}, d_i) \) which is assumed to be a proper density in the sense that

\[
\sum_{d_i = 0, 1} \int_{-\infty}^{\infty} t(V_{2i}, d_i) \, dV_{2i} = 1.
\]

From equations (3b) and (3c), the probability that \( y_{2i}^d \geq 0 \) given \( d_i = 1 \) must be unity, so that one may write

\[
\Pr(V_{2i} > l_i | d_i = 1) = 1
\]

where the symbols \( l \) and \( l' \) are defined by

\[
l = -(X_{1i} \pi_{21} + X_{2i} \pi_{22} + \pi_{23})
\]

and

\[
l' = l + \pi_{23}.
\]

Alternatively, one may write this condition as

\[
(4a) \quad \int_{-\infty}^{\infty} t(V_{2i}, 1) \, dV_{2i} = P_i
\]

and obviously

\[
(4b) \quad \int_{-\infty}^{l_i} t(V_{2i}, 1) \, dV_{2i} = 0.
\]

Using similar reasoning, one can conclude that

\[
(4c) \quad \int_{-\infty}^{l'_i} t(V_{2i}, 0) \, dV_{2i} = 1 - P_i
\]

and

\[
(4d) \quad \int_{l_i}^{\infty} t(V_{2i}, 0) \, dV_{2i} = 0.
\]

The sum of the left hand side terms of equations (4a)–(4d) equals the sum of the right hand side terms which should equal one if the probability of the event
$d_i = 1$ is meaningfully defined. If $\pi_{23} = 0$, this is the case. But if $\pi_{23} < 0$, the sum of the left hand side terms falls short of one while if $\pi_{23} > 0$, this sum exceeds one. Q.E.D.

Notice that this argument does not rely on the assumption that $V_{2i}$ is normally distributed but does rely on the assumption that $V_{2i}$ has positive density at almost all points on the real line.

An intuitive motivation for this condition is possible. Suppose that one rewrites equations (1a)–(1c) to exclude $d_i$, i.e., write

$$ y_{1i}^* = X_1 \alpha_1 + y_{2i}^* \gamma_1 + U_{1i}, $$

$$ y_{2i}^* = X_2 \alpha_2 + y_{1i}^* \gamma_2 + U_{2i}, $$

$$ d_i = 1 \text{ iff } y_{2i}^* > 0, $$

$$ d_i = 0 \text{ otherwise.} $$

Note that $y_{1i}^*$ is an unobserved latent variable. The random variable $y_{1i}$ is observed and is defined by the following equation:

$$ y_{1i} = y_{1i}^* + d_i \beta_1. $$

Making the appropriate substitutions of $y_{1i}$ for $y_{1i}^*$ in the system given above, one concludes that

$$ y_{1i} = X_1 \alpha_1 + d_i \beta_1 + y_{2i}^* \gamma_1 + U_{1i}, $$

$$ y_{2i}^* = X_2 \alpha_2 + (y_{1i} - d_i \beta_1) \gamma_2 + U_{2i}. $$

Invoking the principal assumption, one reaches equations (1a)–(1c) including $d_i$. Thus the dummy shift variable $d_i \beta_1$ may be viewed as a veil that obscures measurement of the latent variable $y_{1i}^*$. The principal assumption essentially requires that the latent variable $y_{1i}^*$ and not the measured variable $y_{1i}$ appears in the second structural equation. It is possible to use the latent variable in the second equation because $\beta_1$ can be estimated as will be shown below.

It is important to note that the principal assumption does not rule out structural shift in equations (1a) and (1b). It simply restricts the nature of the shift. However, the principal assumption does exclude any structural shift in the reduced form equation that determines the probability of a shift (equation (3b)).

(ii) Identification of Parameters: Indirect Least Squares Estimators

Given the principal assumption, equation system (3a)–(3c) may be written as

$$ y_{1i} = X_1 \pi_{11} + X_2 \pi_{12} + P \pi_{13} + V_{1i} + (d_i - P) \pi_{13}, $$

$$ y_{2i}^* = X_1 \pi_{21} + X_2 \pi_{22} + V_{2i}, $$

$$ d_i = 1 \text{ iff } y_{2i}^* > 0, $$

$$ d_i = 0 \text{ otherwise.} $$

$\pi_{11} \neq 0$, $\pi_{12} \neq 0$, $\pi_{21} \neq 0$, $\pi_{22} \neq 0$. 

Estimation of equation (5b) is a problem in probit analysis. Subject to the standard requirements for identification and existence of probit estimates (see Nerlove and Press [22]), one may normalize by $\omega_2^{1/2}$ and estimate
\begin{equation}
\pi_{21}^* = \frac{\pi_{21}}{(\omega_{22})^{1/2}}, \quad \pi_{22}^* = -\frac{\pi_{22}}{(\omega_{22})^{1/2}},
\end{equation}
by using the reduced form probit function to estimate the conditional probabilities of the events $d_i = 1$ and $d_i = 0$.

To determine how to estimate the parameters of the equation (5a), it is useful to write the conditional expectation of $y_{1i}$ given $d_i, X_{1i}$ and $X_{2i}$ i.e.,
\begin{equation}
E(y_{1i} | X_{1i}, X_{2i}, d_i) = X_{1i}\pi_{11} + X_{2i}\pi_{12} + d_i\pi_{13} + E(V_{1i} | d_i, X_{1i}, X_{2i}).
\end{equation}

Utilizing a result familiar in the theory of biserial correlation (see, e.g., Tate [27] or Johnson and Kotz [13, Vol. 4]),
\begin{equation}
E(V_{1i} | d_i, X_{1i}, X_{2i}) = \frac{\omega_{12}}{(\omega_{22})^{1/2}}(\lambda_i d_i + \tilde{\lambda}_i (1 - d_i))
\end{equation}
where
\begin{equation}
\lambda_i = \frac{\phi(c_i)}{1 - \Phi(c_i)}
\end{equation}
with $c_i = -(X_{1i}\pi_{21}^* + X_{2i}\pi_{22}^*)$, where $\phi$ and $\Phi$ are the density and distribution function of a standard normal random variable and
\begin{equation}
\tilde{\lambda}_i = -\lambda_i \left[ \frac{\Phi(-c_i)}{\Phi(c_i)} \right].
\end{equation}

If one knew, or could estimate, $E(V_{1i} | d_i, X_{1i}, X_{2i})$, it could be entered as a regressor in equation (7) and parameters $\pi_{11}, \pi_{12}, \pi_{13},$ and $\omega_{12}^{1/2} = \omega_{12} / (\omega_{22})^{1/2}$ could be estimated by standard least squares methods. Since the normalized parameters of equation (5b) are estimable, so is $c_i$ and hence $\lambda_i, \tilde{\lambda}_i,$ and $E(V_{1i} | d_i, X_{1i}, X_{2i}).$ Elsewhere (Heckman [11]) it is shown that use of estimated values of $\lambda_i$ and $\tilde{\lambda}_i$ instead of actual values as regressors in equation (7) leads, under general conditions, to consistent parameter estimators of all the regression coefficients in that equation.

Given this result, all of the parameters of equation (7) are estimable. Note in particular that the correlation between $V_{1i}$ and $V_{2i}/\omega_{12}^{1/2} = V_{2i}^*$ is also estimable even though there are no direct observations on $y_{2i}^*$. This result is a familiar one in the theory of biserial correlation.\footnote{Note that the use of the estimated value of $E(V_{1i} | d_i, X_{1i}, X_{2i})$ as a regressor to estimate the parameters of the disturbance covariance structure closely parallels Telser's [28] procedure of utilizing least squares residuals from other equations in a system of equations to estimate the parameters of the inter-equation covariance structure.}

To see how to estimate the reduced form variance, $\omega_{11}$, note that the general model, of which equation (7) is the conditional expectation, may be written as
\begin{equation}
y_{1i} = E(y_{1i} | X_{1i}, X_{2i}, d_i) + \eta_i
\end{equation}
where

\[ E(\eta_i | X_{1i}, X_{2i}, d_i) = 0 \]

and

\[ E(\eta_i^2 | X_{1i}, X_{2i}, d_i) = \omega_{11}[(1 - \rho^2) + \rho^2(d_i q_i + (1 - d_i)s_i)] \]

where

\[ \rho = \frac{\omega_{12}}{(\omega_{11} \omega_{22})^{\frac{1}{2}}} \]

\[ q_i = 1 + \lambda_i c_i - \lambda_i^2 \]

\[ s_i = 1 - \lambda_i c_i - \lambda_i^2. \]

(See Johnson and Kotz [13, Vol. 4].)

Since \( \omega_{11}^* \) can be consistently estimated, and since \( \omega_{12}^* = (\omega_{11})^j \rho \), a consistent estimator of \( \omega_{11} \) is possible using the estimated residuals from least squares estimates of equation (8). Denote the estimated residual for observation \( i \) by \( \hat{\eta}_i \). Then estimate \( \omega_{11} \) from the following formula:

\[ \hat{\omega}_{11} = \frac{1}{I} \sum_{i=1}^{I} \hat{\eta}_i^2 + (\omega_{12}^*)^2 \left[ 1 - \frac{1}{I} \left( \sum_{i=1}^{I} d_i q_i + (1 - d_i)s_i \right) \right] \]

where estimated values of \( q_i \) and \( s_i \) are used in place of actual values. This estimator is consistent.\(^7\)

Given consistent estimators of reduced form coefficients, estimators of the structural parameters are easily obtained. Since the coefficient of equation (5b) can only be estimated up to an unknown constant of proportionality, \( \omega_{12}^j \), it is not possible to estimate all of the coefficients of equations (1a) and (1b). Some of these coefficients can only be estimated up to an unknown constant of proportionality.

From equation (2), it is clear that if some exogenous variables appear in equation (1a) that do not appear in (1b) it is possible to estimate \( \gamma_2^* = \gamma_2 / \omega_{22}^j \). Take the \( j \)th variable in \( X_{1i} \), denoted \( X_{1i,j} \), and its associated estimable reduced form coefficients \( \pi_{1i} \) and \( \pi_{2i,j} \). Assume that this variable is not included in \( X_{2i} \). Taking the ratio of the estimator of the second coefficient to the estimator of the first yields a consistent estimator of \( \gamma_2^* \):

\[ \hat{\gamma}_2^* = \frac{\hat{\pi}_{2i,j}^*}{\hat{\pi}_{1i}^*}, \quad j = 1, \ldots, J_1. \]

where "\(^*\)" denotes an estimate and where \( J_1 \) is the number of variables in \( X_{1i} \) not contained in \( X_{2i} \), adopting the harmless convention that the first \( J_1 \) variables in \( X_{1i} \) are such variables. Similarly, one may consistently estimate \( \gamma_1(\omega_{22})^j = \gamma_1^* \) if some variables included in \( X_{2i} \) do not appear in \( X_{1i} \). Utilizing notation

\(^7\) Further, it is guaranteed to be positive. One can prove that the second term on the right hand side must be positive.
previously introduced,

\[ \tilde{\gamma}_{12j} = \gamma_{12j} = \gamma_{1j}^\ast, \quad j = 1, \ldots, J, \]

where \( J \) is the number of variables in \( X_{2i} \) not contained in \( X_{1i} \) and the first \( J \) variables in \( X_{2i} \) are assumed not to be included in \( X_{1i} \).

In general, the model will be overidentified if it is identified at all. The procedure for resolving the overidentification problem is entirely conventional and will be discussed below. Assume, for the moment, that this problem can be resolved. Given unique estimators of \( \gamma_{1j}^\ast \) and \( \gamma_{2j}^\ast \), one can exploit the information in equations (2) and (6) to estimate

\[ \alpha_1, \quad \alpha_2(\omega_2) = \alpha_2^\ast, \quad \beta_2(\omega_2) = \beta_2^\ast, \quad \text{and} \quad \beta_1. \]

The only parameters that remain to be identified are the disturbance covariance terms of the structural equations. Without further information, it is not possible to estimate all of the parameters of the structural equation covariance matrix, just the parameters \( \sigma_{11}, \sigma_{12}, \sigma_{22} = \sigma_{22} \).

To see this, note that

\[ \omega_{11} = E(V_{1i}^2) = \frac{\sigma_{11} + 2\gamma_{12}\sigma_{12} + \gamma_{12}^2\sigma_{22}}{(1 - \gamma_{1}\gamma_{2})^2}, \]

\[ \omega_{12} = E(V_{1i}V_{2i}) = \frac{\gamma_{12}\sigma_{11} + (\gamma_{2}^\ast)\sigma_{12} + \gamma_{1}\sigma_{22}}{(1 - \gamma_{1}\gamma_{2})^2}, \]

\[ \omega_{22} = E(V_{2i}^2) = \frac{\sigma_{22} + 2\gamma_{2}\sigma_{12} + \sigma_{22}^2}{(1 - \gamma_{1}\gamma_{2})^2}, \]

Since \( \gamma_{1}, \gamma_{2}, \gamma_{1}^\ast, \) and \( \gamma_{2}^\ast \) are estimable parameters, and since consistent estimators of the left hand side terms of equations (9) and (10) are available, these equations, supplemented by equation (11), provide three linear equations in the three unknowns \( \sigma_{11}, \sigma_{12}, \sigma_{22}^\ast \). In general, these equations can be solved for unique estimators.

(iii) Maximum Likelihood Estimators

The preceding analysis not only yields criteria for the identification of structural coefficients but also produces consistent estimators for identified

\[ 1 = E(V_{2i}^2) = \frac{(\gamma_{2}^\ast)^2\sigma_{11} + 2(\gamma_{2}^\ast)\sigma_{12} + \sigma_{22}^\ast}{(1 - \gamma_{1}\gamma_{2})^2}. \]

This final restriction was suggested to me by Professor L. Lee.
coefficients. These estimators are useful for providing estimates enroute to deriving maximum likelihood estimators, but they are not, in general, efficient. The maximum likelihood estimator that is discussed next is asymptotically efficient.

The density function for the disturbances $V_{1i}, V_{2i}$ is bivariate normal. For notational simplicity normalize $V_{2i}$ by $\omega_{22}^{\frac{1}{2}}$ and define $V_{2i}^* = V_{2i} \omega_{22}^{\frac{-1}{2}}$. The joint density of $V_{1i}, V_{2i}^*$ is $h(V_{1i}, V_{2i}^*)$. Since $d_i = 1$ iff $y_{2i}^* > 0$ and $d_i = 0$ otherwise, the density of $y_{1i}, d_i$ is given by

$$f(y_{1i}, d_i) = \left[ \int_{c_i}^{\infty} h(y_{1i} - X_{1i} \pi_{11} - X_{2i} \pi_{12} - \pi_{13}, V_{2i}^*) \, dV_{2i}^* \right]^{d_i} \cdot \left[ \int_{-\infty}^{c_i} h(y_{1i} - X_{1i} \pi_{11} - X_{2i} \pi_{12} - \pi_{13}, V_{2i}^*) \, dV_{2i}^* \right]^{1-d_i}$$

where $c_i$ has previously been defined as

$$c_i = -(X_{1i} \pi_{21}^* + X_{2i} \pi_{22}^*).$$

Using equation (2), the density may be rewritten in terms of identified structural parameters.

Assuming random sampling, the likelihood function for the hybrid model with structural shift is

$$\mathcal{L} = \prod_{i=1}^{I} f(y_{1i}, d_i),$$

where $I$ is sample size. Under conditions specified below, this function possesses an optimum, and the maximum likelihood estimators have desirable large sample properties. The identification procedure previously discussed provides an algorithm for generating initial consistent estimators so that one Newton step produces asymptotically efficient estimators. These initial estimators are particularly valuable because likelihood function (13) is not a globally concave function of the structural parameters.

Note that if $\omega_{12} = 0$, so that the reduced form disturbances $V_{1i}$ and $V_{2i}^*$ are independent, density $h(V_{1i}, V_{2i}^*)$ factors into a product of marginal densities $h_1(V_{1i})h_2(V_{2i}^*)$ and $f(y_{1i}, d_i)$ becomes

$$f(y_{1i}, d_i) = h_1(y_{1i} - X_{1i} \pi_{11} - X_{2i} \pi_{12} - \pi_{13}d_i) \cdot \left[ \int_{c_i}^{\infty} h_2(V_{2i}^*) \, dV_{2i}^* \right]^{d_i} \cdot \left[ \int_{-\infty}^{c_i} h_2(V_{2i}^*) \, dV_{2i}^* \right]^{1-d_i}$$

so that regression estimators of equation (5a) and probit estimators of equation (5b) are maximum likelihood estimators of the reduced form parameters. In most practical problems the assumption that $\omega_{12} = 0$ is untenable.

---

9 For a discussion of this rather unusual density, see Appendix A.
In addition to the ordinary identification conditions previously discussed, another condition is required in order for likelihood function (13) to possess a well defined maximum with respect to its parameters. In order to understand this condition, it is helpful to use conditional normal theory to write density \( f(y_{1i}, d_i) \) as

\[
f(y_{1i}, d_i) = h_1(y_{1i} - X_1 \pi_{11} - X_2 \pi_{12} - d_i \pi_{13}) [\Phi(r_i)]^{d_i} [\Phi(-r_i)]^{1-d_i}
\]

where \( \Phi \) is the cumulative distribution of the univariate normal, and

\[
r_i = c_i - \rho \left( \frac{V_{1i}/\sigma_{11}}{(1-\rho^2)^{\frac{1}{2}}} \right)
\]

where

\[
V_{1i} = y_{1i} - X_1 \pi_{11} - X_2 \pi_{12} - d_i \pi_{13}
\]

and

\[
\rho = \frac{\sigma_{12}}{(\sigma_{11} \sigma_{22})^{\frac{1}{2}}}
\]

This representation of the density is both computationally and theoretically convenient.

In a sample of size \( I \), classify the observations into two groups depending on whether or not the dummy variable \( d_i \) is one. Among the \( I_1 \) observations with \( d_i = 1 \), denote the smallest \( r_i \) by \( r_i^{(1)} \) min., and the largest by \( r_i^{(1)} \) max. Among the \( I_0(= I - I_1) \) observations with \( d_i = 0 \), denote the largest \( r_i \) by \( r_i^{(0)} \) max, and the smallest by \( r_i^{(0)} \) min. Then, likelihood function (13) possesses no interior optimum in a compact parameter set if

\[
r_i^{(0)} \max \leq r_i^{(1)} \min \quad \text{or if} \quad r_i^{(0)} \min \geq r_i^{(1)} \max
\]

so that there is no overlap among the values of the \( r_i \) classified by the occurrence of the event.\(^{10}\)

This condition arises in standard probit analysis (see Nerlove and Press [22]). To understand it, consider estimates of an ordinary probit model. If any variable perfectly classifies the outcome of a discrete event, the coefficient of that variable becomes unbounded and is not identified. This phenomenon may arise in the current problem even if no exogenous variable (or linear combination of exogenous variables) perfectly classifies outcomes because of the presence of random variable \( V_{1i} \) in \( r_i \). There is a positive probability that condition (14) will be met and maximum likelihood estimators will fail to exist. However, using standard results in the theory of order statistics, it is trivial to establish that the probability that condition (14) is met tends to zero if sample size expands by

\(^{10}\) A similar condition arises in the conditional logit model. See McFadden [19, Appendix].
"fixed in repeated samples" sampling.\textsuperscript{11} Given their existence, maximum likelihood estimators are consistent, asymptotically normal, and efficient.\textsuperscript{12}

(iv) \textit{Some Alternative Estimators}

Since maximum likelihood estimation is computationally cumbersome, it is useful to consider alternative estimators for the hybrid model. In addition, the problem of the multiplicity of consistent estimators that arises in an over-identified model remains to be resolved. It will be shown that the fact that $y^{*}_{2t}$ is never observed has important consequences that cause the analysis in this paper to differ dramatically from that in conventional simultaneous equation theory.

\textsuperscript{11} Briefly consider the condition $r_{f}^{(0)} \leq r_{f}^{(1)} \min$. If one data configuration (i.e., a choice of $X_{1i}, X_{2i}$) is considered and the number of observations on that configuration becomes large, the condition becomes

\[
\max \left( \frac{-\rho}{(1-\rho^2)} V_{1i}^{(i)} \right)_{i=1}^{l} \leq \min \left( \frac{-\rho}{(1-\rho^2)} V_{1i}^{(0)} \right)_{i=1}^{l}
\]

where $V_{1i}$ is random variable $V_{1i}$ conditional on $d_{i} = 1$ while $V_{1i}^{(0)}$ is random variable $V_{1i}$ conditional on $d_{i} = 0$. One may write $V_{1i}^{(i)} = k_{i} + \eta_{1i}$ and $V_{1i}^{(0)} = k_{0} + \eta_{2i}$, $t = 1, \ldots, I_{t}, i' = 1, \ldots, I_{0}$, where $\eta_{1i}$ and $\eta_{2i}$ are continuous independent random variables. The probability that $\eta_{1i} - \eta_{2i} > k_{0} - k_{1}$ is less than one for any pair of observations from the disjoint sets. Hence, in large samples, condition $r_{f}^{(0)} \leq r_{f}^{(1)} \min$ occurs with probability zero.

\textsuperscript{12} It is a straightforward exercise to verify that LeCam's \cite{17} generalization of the classical Cramer conditions applies to the model in the text for suitably chosen values of the parameters. These conditions are local in nature and imply the existence of some root of the likelihood equations that is consistent and asymptotically normally distributed. Olsen \cite{23} verifies the LeCam conditions for a model based on the one in the text. Olsen's structural model is the reduced form of the current model with the exception that $\pi_{13}$ is set at zero in his work. His proofs carry over to the more general case.

One point is not obvious, and is not covered in Olsen's work. Since a model with $\pi_{13} \neq 0$ superficially resembles the model advanced by Aigner, Amemiya and Poirier \cite{1} to demonstrate the superefficiency of maximum likelihood estimators for the parameters of a discontinuous density, it is worth verifying that the expectation of the first partial of the log of the density of $f(y_{1i}, d_{i})$ with respect to $\pi_{13}$ vanishes when the expectation is taken with respect to the density evaluated at the true parameter values.

Denote $E_{0}$ as the expectation taken with respect to the density of $y_{1i}$ and $d_{i}$ when the true parameters are used in the density. Let $V_{1i} = y_{1i} - X_{1i} \pi_{11} - X_{2i} \pi_{12} - d_{i} \pi_{13}$. Then

\[
E_{0} \left[ \frac{\partial \ln f(y_{1i}, d_{i})}{\partial \pi_{13}} \right] = E_{0} \left[ \frac{d_{i}}{(1-\rho^2)} \int_{0}^{\infty} \frac{V_{1i}^{*}}{\omega_{1i}} h(V_{1i}, V_{2i}^{*}) dV_{2i}^{*} \right]
\]

Since

\[
\int_{0}^{\infty} \int_{0}^{\infty} \frac{V_{1i}^{*}}{\omega_{1i}} h(V_{1i}, V_{2i}^{*}) dV_{2i}^{*} dV_{1i} = \rho \int_{0}^{\infty} \int_{0}^{\infty} \frac{V_{2i}^{*}}{\omega_{2i}} h(V_{1i}, V_{2i}^{*}) dV_{2i}^{*} dV_{1i}
\]

(see, e.g., Johnson and Kotz \cite{13, Vol. 4}), it follows that

\[
E_{0} \left[ \frac{\partial \ln f(y_{1i}, d_{i})}{\partial \pi_{13}} \right] = 0
\]

as desired.
Consider equations (1a)–(1c), rewritten below to facilitate the exposition. Because it is assumed that $y_{1i}^*$ is observed, it is replaced by $y_{1i}$. With this change, the equations become

\begin{align*}
(1a) & \quad y_{1i} = X_1\alpha_1 + d_i\beta_1 + y_{2i}^*\gamma_1 + U_{1i}, \\
(1b) & \quad y_{2i}^* = X_2\alpha_2 + d_i\beta_2 + y_{1i}\gamma_2 + U_{2i},
\end{align*}

where dummy variable $d_i$ is defined by

\begin{align*}
(1c) & \quad d_i = 1 \text{ iff } y_{2i}^* > 0, \\
& \quad d_i = 0 \text{ otherwise},
\end{align*}

and the principal assumption is invoked so that $\gamma_2\beta_1 + \beta_2 = 0$.

Using the results of the previous analysis, it is possible to estimate equations (1a) and (1b) directly using the reduced form coefficient estimates to generate instruments. To see this, note that it is possible to use equation (5b) to estimate the expectation of $y_{2i}^*/\omega_{22}$ conditional on $X_{1i}$ and $X_{2i}$:

$$\text{E}(y_{2i}^*/\omega_{22}) = X_1\hat{\alpha}_2 + X_2\hat{\beta}_2.$$ 

From the probit estimator of (5b) it is possible to estimate the probability of the event $d_i = 1$ conditional on values of $X_{1i}$ and $X_{2i}(\hat{P}_i)$. Replacing $y_{2i}^*$ and $d_i$ by their estimated expectations, equation (1a) becomes

\begin{align*}
(1a') & \quad y_{1i} = X_1\alpha_1 + \hat{P}_i\beta_1 + (\text{E}(y_{2i}^*/\omega_{22}))\gamma_1 + U_{1i} + (d_i - \hat{P}_i)\beta_1 \\
& \quad \quad \quad \quad \quad + \gamma_1^*(y_{2i}^*/\omega_{22} - \text{E}(y_{2i}^*/\omega_{22})).
\end{align*}

Least squares applied to equation (1a') yields unique consistent estimators of $\alpha_1$, $\beta_1$, and $\gamma_1^*$. The proof is trivial and hence is omitted. Estimation of this equation resolves the problem of the multiplicity of estimators that arises from the application of indirect least squares discussed in part (ii).

Precisely the same procedure may be used to estimate the parameters of equation (1b). There is one new point. The choice of a normalization rule in a simultaneous equation system is usually arbitrary. Here the choice is important because $y_{2i}^*$ is never observed, although its expectation can be estimated. In equations (1a) and (1b), $y_{1i}$ is selected as the dependent variable. Substituting estimated conditional means for endogenous variables, equation (1b) may be written as

\begin{align*}
(1b') & \quad y_{1i} = \frac{1}{\gamma_2^*}(X_{2i}\alpha_2^* + \hat{P}_i\beta_2^* - (y_{2i}^*/\omega_{22}^-)) \\
& \quad \quad \quad - \frac{1}{\gamma_2^*} (U_{2i}\omega_{22}^- + (d_i - \hat{P}_i)\beta_2^* - (y_{2i}^*/\omega_{22}^- - \text{E}(y_{2i}^*/\omega_{22}^-))).
\end{align*}

It is straightforward to prove that least squares estimators of equation (1b') are consistent.
There is one further problem. Although the principle assumption requires \( \gamma_2 \beta_1 + \beta_2 = 0 \), this constraint is not imposed in the preceding analysis. One way to impose the constraint is to estimate equation (1a') and use the fitted value of \( \beta_2^* / \gamma_2^* (-\beta_1) \) as a parameter in equation (1b'). A more satisfactory approach that is computationally more burdensome is to impose the constraint directly in formulating joint least squares estimators for equations (1a') and (1b').

It is tempting to use the residuals computed from the fitted equations (1a') and (1b') to directly estimate the structural covariance terms \( \sigma_{11}, \sigma_{12}^*, \) and \( \sigma_{22}^* \). A direct application of structural two stage least squares formulae will not work precisely because \( \hat{y}_{21}^* \) is never observed. If estimated values of \( \hat{y}_{21}^* \) are used in place of actual values, the residuals from (1c) and (1b) will not permit identification of the structural covariances.

One method for circumventing this difficulty is to use the estimated structural parameters to solve for the reduced form parameters \( \pi_{21}^*, \pi_{22}^*, \pi_{11}, \pi_{12}, \) and \( \pi_{13}^* \). These estimates may be treated as known parameters in estimating equation (7). Hence it is possible to estimate \( \omega_{11} \) and \( \omega_{12} \omega_{22}^{-\frac{1}{2}} \), and by use of equations (9), (10), and (11) to obtain unique consistent estimators of \( \sigma_{11}, \sigma_{12}^*, \) and \( \sigma_{22}^* \).

While these estimators are simply computed, consistent, and free of the nonuniqueness problem that plagues indirect least squares estimators in the overidentified case, they are not asymptotically efficient nor are their asymptotic distributions simple. The standard formulae used for the computation of large sample parameter variances is inappropriate. This is so because \( \hat{y}_{2i}^* \omega_{22}^{-\frac{1}{2}} \) is never directly observed and only an estimated value of this variable is available.

To understand these difficulties, it is useful to discuss two special cases that are of interest in practical empirical work. First consider estimation of equation (1a) when \( \beta_1 = 0 \) so that no direct structural shift is present in that equation. Then consider a case in which \( \gamma_1 = 0 \) so that no unobserved latent variable is present in equation (1a). In both cases consistent parameter estimators are available, as has been shown.

Consider the disturbance from equation (1a') under the assumption that \( \beta_1 = 0 \). Denote the composite disturbance by \( \hat{U}_{1i} \)

\[
\hat{U}_{1i} = U_{1i} + \gamma_1^* (\hat{y}_{2i}^* \omega_{22}^{-\frac{1}{2}} - \hat{y}_{2i} \omega_{22}^{-\frac{1}{2}}).
\]

The crucial feature of these residuals is that they are not independent across observations nor are they identically distributed. Accordingly, standard central limit theorems do not apply to regression coefficient estimators of equation (1a'). In particular, it is not the case that the standard estimator of the regression parameter variance-covariance matrix,

\[
\hat{\sigma}_{11} \left( \frac{\sum X_{1i}X_{1i}^*}{\sum \hat{y}_{2i}^* \omega_{22}^{-\frac{1}{2}}} \right)^{-1} \left( \frac{\sum \hat{y}_{2i}^* \omega_{22}^{-\frac{1}{2}}}{\sum \hat{y}_{2i} \omega_{22}^{-\frac{1}{2}}} \right)^{-1}
\]

is the appropriate asymptotic variance-covariance matrix for the regression coefficients.

---

13 I owe this point to Tom Macurdy.
The source of the problem comes in the final term in $\hat{U}_{1i}$. Utilizing the reduced form for $y^*_{2i|22}$, this term becomes

$$y^*_{2i|22} - \hat{y}^*_{2i|22} = X_{1i}(\pi^*_{21} - \hat{\pi}^*_{21}) + X_{2i}(\pi^*_{22} - \hat{\pi}^*_{22}) + V_{1i}.$$  

$V_{1i}$ is an iid random variable. But the first two terms are not iid. Since $\hat{\pi}^*_{21}$ and $\hat{\pi}^*_{22}$ are maximum likelihood estimators, they possess asymptotic normal limiting distributions, and in large samples the first two terms converge in probability to zero. But their rate of convergence is not fast enough.

In fact, regression estimators of equation (1a') with $\beta_1 = 0$ obey the following relationship:

$$\sqrt{I}(\hat{\alpha}_1 - \alpha_1) = \left[\frac{1}{I}\left(\sum X_{1i}X'_{1i} \sum X'_{1i}(\hat{y}^*_{2i|22})^2 \right) \sum (\hat{y}^*_{2i|22})^2 \right]^{-1} \cdot \left[\frac{1}{\sqrt{I}}\left(\sum X'_{1i}(U_{1i} + V_{1i}) \sum (\hat{y}^*_{2i|22})(U_{1i} + V_{1i}) \right) \sum (\hat{y}^*_{2i|22}) \right]^{-1} \cdot \left[\sum (X_{1i}(X_{1i}[\pi^*_{2i} - \hat{\pi}^*_{21}] + X_{2i}[\pi^*_{22} - \hat{\pi}^*_{22}]) \sum (\hat{y}^*_{2i|22})(X_{1i}[\pi^*_{2i} - \hat{\pi}^*_{21}] + X_{2i}[\pi^*_{22} - \hat{\pi}^*_{22}]) \right].$$

Both terms on the right hand side converge to proper normal random variables.\(^\text{14}\) Accordingly, the standard formula for the asymptotic variance-covariance matrix is inapplicable. Although the correct asymptotic variance-covariance matrix can be estimated, the computational burden of doing so in a general case is greater than direct optimization of the likelihood function.

Now turn to the second case. Consider the estimation of equation (1a') for a case in which $\gamma_i = 0$ so that no latent variable is present in equation (1a). The analysis of this case is thoroughly conventional.

The estimated reduced form probability $\hat{P}_i$ may be used as an instrumental variable for $d_i$. Standard instrumental variable formulas may be used to estimate the appropriate asymptotic variance-covariance matrix of the coefficients.

The procedure to be used is as follows. $\hat{P}_i$ may be employed as an instrument for $d_i$ in equation (1a'), and consistent estimators of $\alpha_1$ and $\beta_1$ may be produced. Using actual values for $d_i$, and the estimated coefficients, one may estimate the residuals for each observation which, when squared, summed, and divided by $I$, yield an estimator of $\sigma_{1i}$. The appropriate asymptotic variance-covariance matrix for the regression coefficients $\alpha_1, \beta_1$ may be consistently estimated by the standard instrumental variable formula:

$$\hat{\sigma}_{1i} \left(\sum X_{1i}X'_{1i} \sum d_i \hat{P}_i \right)^{-1} \left(\sum X_{1i}X'_{1i} \sum X'_{1i} \hat{P}_i \right)^{-1} \left(\sum X_{1i}X'_{1i} \sum d_i \hat{P}_i \right)^{-1} \left(\sum X_{1i}X'_{1i} \sum d_i \hat{P}_i \right)^{-1}.$$

Note that since the residuals from the prediction of $d_i(d_i - \hat{P}_i)$ are not guaranteed to be orthogonal to the $X_{1i}$ regressors, the instrumental variable formula is not equivalent to the standard two stage least squares formula, and the instrumental

\(^{14}\) The proof is straightforward. See Heckman [11, Appendix A] for a more complete discussion.
variable estimator is not equivalent to the standard two stage least squares estimator.\textsuperscript{15}

Note further that if the sole purpose of the analysis is to estimate equation (1a), it is not necessary to estimate probit functions at all. It is possible to generate an instrumental variable for $d_i$ by estimating a simple linear probability model with $d_i$ as a dependent variable that contains at least all of the variables in $X_{1i}$ and some other exogenous variable as regressors.\textsuperscript{16} If these estimators are utilized, the standard two stage least squares procedure applies and predicted values of $d_i$ may be utilized as regressors since in this case the regression residuals from the prediction of $d_i$ are constructed to be orthogonal to the $X_{1i}$ regressors. This result simply restates the well known point that it is unnecessary to obtain consistent estimators of the parameters of reduced form equations in order to consistently estimate structural equations.

Since the linear probability procedure is the simplest one to use, it is recommended. However, it is likely that the use of the probit instrument results in more efficient estimators although no proof of this assertion is offered.

The discussion of these two cases is illuminating. For both cases simply computed consistent parameter estimators are available. In the first case, with an unobserved random variable present, the estimators converge to a normal distribution but the theoretically appropriate asymptotic covariance matrix is cumbersome to compute. In this case it is suggested that analysts utilize the consistent estimators discussed in this section as starting values for at least one Newton step towards the likelihood optimum to produce estimators with desirable large sample properties.\textsuperscript{17} The second case requires only a simple application of conventional instrumental variable estimator theory. For both cases and in the general case that contains both special cases, full system maximum likelihood estimation will produce asymptotically efficient estimators and is certainly recommended for all but the special second case.

The hybrid model can be generalized in several ways. Two extensions are particularly important. First, several dummy indicator variables can be introduced into the model. Two types of multiple dummy shift variables can be introduced. The first type of dummy variable represents a polytomization of a single latent variable and is appropriate for the case of ordered dichotomous variables. The second type is for an intrinsically unordered case.\textsuperscript{18} These models, and obvious multivariate extensions, are briefly discussed in Appendix B. Second, the random variable $y_{1i}$ may be a truncated variable. This case, which nests Tobin's model [29] into a simultaneous equation system, can be analyzed by a direct application of the previous analysis and hence is not discussed here.\textsuperscript{19}

\textsuperscript{15} See Sant [26].
\textsuperscript{16} This follows directly from the analysis of Kelejian [15].
\textsuperscript{17} A copy of a computer program to produce both one step Newton iterates and full information maximum likelihood estimates is available, on request, from the author for the cost of duplication, postage, and handling charges.
\textsuperscript{18} An important reference for such models is Amemiya [2].
\textsuperscript{19} This extension is performed in an unpublished Ph.D. thesis at the University of Chicago; see L. Olson [24]. For a further elaboration of this model, see F. Nelson and L. Olson [21].
3. MULTIVARIATE PROBIT MODELS WITH STRUCTURAL SHIFT

In this section multivariate probit models are discussed. In these models there are no observed latent variables so that the only information available is that $y_{1i}^* \geq 0$ and $y_{2i}^* \geq 0$. These models are superficially different from those considered in the analysis of the hybrid model. Appearances are deceiving. Both models are generated from underlying continuous latent variables and the analysis of one model readily applies to the analysis of the other.

Equations (1a)–(1c) apply to this case as well. As before, $d_i$ is defined as the dichotomization of $y_{2i}^*$:

$$ d_i = 1 \quad \text{iff} \quad y_{2i}^* \geq 0, $$

$$ d_i = 0 \quad \text{otherwise,} $$

and define dummy variable $a_i$ as the dichotomization of $y_{1i}^*$:

$$ a_i = 1 \quad \text{iff} \quad y_{1i}^* \geq 0, $$

$$ a_i = 0 \quad \text{otherwise.} $$

(15)

The argument of Section 2 may be applied to this case.

As in the case of the hybrid model, the principal assumption $(\gamma_2 \beta_1 + \beta_2 = 0)$ is a requirement for a meaningful statistical model to exist. Accordingly, the argument of Section 2, part (i) of this paper applies to the multivariate probit model. The models of Ashford and Sowden [3], Amemiya [2], and Zellner and Lee [30] satisfy this assumption since none of these papers considers structural shift in the equations (i.e., they assume that $\beta_1 = \beta_2 = 0$).

The identification procedure in Section 2, part (ii) must be modified since no observations are available on $y_{1i}$. The analysis of identification of $\pi_{11}^*$ and $\pi_{22}^*$ is as before. But the analysis of equation (5a) must be modified. Two distinct cases are worth considering. First suppose that $\pi_{13} = 0$ so that there is no structural shift in the equations.

In this case, normalized parameters of equation (5a) may be estimated. That is, one may use probit analysis to estimate

$$ \pi_{11}^* = \frac{\pi_{11}}{(\omega_{11})^\frac{1}{2}} \quad \text{and} \quad \pi_{12}^* = \frac{\pi_{12}}{(\omega_{11})^\frac{1}{2}}. $$

The correlation between $V_{1i}$ and $V_{2i}$ may also be estimated, even though both $y_{1i}^*$ and $y_{2i}^*$ are latent variables. This result is well known in the theory of tetrachoric correlation (Kendall and Stuart [16, Vol. II]). To establish this result it is useful to recall that $c_i$ is defined as

$$ c_i = -(X_{1i} \pi_{21}^* + X_{2i} \pi_{22}^*). $$

and that $b_i$ can be defined as

$$ b_i = -(X_{1i} \pi_{11}^* + X_{2i} \pi_{12}^*). $$
The probability of the events \( a_i \) and \( d_i \) can be written as

\[
(16a) \quad P_{11}(i) = \text{prob} (a_i = 1 \land d_i = 1) = F(-b_i, -c_i, \rho),
\]

\[
(16b) \quad P_{01}(i) = \text{prob} (a_i = 0 \land d_i = 1) = F(b_i, -c_i, -\rho),
\]

\[
(16c) \quad P_{10}(i) = \text{prob} (a_i = 1 \land d_i = 0) = F(-b_i, c_i, -\rho),
\]

\[
(16d) \quad P_{00}(i) = \text{prob} (a_i = 0 \land d_i = 0) = F(b_i, c_i, \rho),
\]

where \( F(\cdot, \cdot) \) is a standardized bivariate normal cumulative distribution.\(^{20}\) Substituting consistent estimators of \( b_i \) and \( c_i \) in place of the true values, these probabilities are solely a function of \( \rho \), the correlation coefficient. The sample likelihood function may be maximized with respect to \( \rho \) to achieve a consistent estimator of that parameter. The appropriate likelihood function is

\[
\mathcal{L}(\rho) = \prod_{i=1}^{I} \left[ P_{11}(i) \right]^{a_{11}(i)} \left[ P_{01}(i) \right]^{a_{01}(i)} \left[ P_{10}(i) \right]^{a_{10}(i)} \left[ P_{00}(i) \right]^{a_{00}(i)} (1-a_{00}(i))^{(1-a_{00}(i))}.
\]

There are alternative minimum chi square estimators and modified minimum chi square estimators for this parameter discussed elsewhere (Amemiya [2]; Heckerman [11]). All of these estimators are consistent but not efficient since the information matrix for the reduced form coefficients is not block diagonal in \( \rho \).

Next suppose that \( \pi_{13} \neq 0 \) so that there is structural shift in reduced form equation (5a). For this case, initial consistent estimators are also available. The conditional distribution of \( a_i \) given \( d_i \) may be written as

\[
\text{prob} (a_i, d_i) = \left[ \begin{array}{c} P_{11}(i) \\ P_{1}(i) \end{array} \right]^{a_{11}(i)} \left[ \begin{array}{c} P_{10}(i) \\ P_{0}(i) \end{array} \right]^{a_{10}(i)} (1-a_{00}(i))^{(1-a_{00}(i))}.
\]

where \( P_0(i) = F(\infty, c_i) \) and \( P_1(i) = 1 - P_0(i) \), and where \( b_i \) is replaced everywhere by \( b'_i \) defined by \( b'_i = b_i - \pi_{13}^* d_i \). Since consistent estimators of \( c_i \) are available, these may be inserted as parameters in the appropriate conditional (on \( d_i \)) likelihood function. If that function is maximized with respect to \( \rho \), \( \pi_{13}^* \), \( \pi_{12}^* \), and \( \pi_{11}^* \), consistent estimators result.\(^{21}\) These estimators are not efficient since the full system information matrix is not block diagonal with respect to these parameters.

This analysis establishes that it is possible to estimate all of the normalized reduced form parameters: \( \rho \), \( \pi_{11}^* \), \( \pi_{12}^* \), \( \pi_{13}^* \), \( \pi_{21}^* \), and \( \pi_{22}^* \). Under the identification hypothesis postulated in Section 1, one can utilize equation (2) to solve for normalized structural parameters

\[
(17) \quad \alpha_1^* = \alpha_1 / \omega_{11}^{\frac{1}{2}}, \quad \beta_1^* = \beta_1 / \omega_{11}^{\frac{1}{2}}, \quad \gamma_1^* = \gamma_1 / \omega_{11}^{\frac{1}{2}} = \gamma_1 \left( \frac{\omega_{22}}{\omega_{11}} \right)^{\frac{1}{2}},
\]

\[
\alpha_2^* = \alpha_2 / \omega_{22}^{\frac{1}{2}}, \quad \beta_2^* = \beta_2 / \omega_{22}^{\frac{1}{2}}, \quad \gamma_2^* = \gamma_2 \omega_{11}^{\frac{1}{2}} = \gamma_2 \left( \frac{\omega_{11}}{\omega_{22}} \right)^{\frac{1}{2}}.
\]

\(^{20}\) Thus, \( F(b_i, c_i, \rho) = \int V_1^* h(V_1^*, V_2^*) \, dV_2^* \, dV_1^* \) \( \), where \( V_1^* = V_1 / \omega_{11}^{\frac{1}{2}} \).

\(^{21}\) Note that it is assumed that \( \pi_{13}^* = 0, \pi_{21}^* = 0, \pi_{11}^* = 0, \) and \( \pi_{12}^* = 0 \).
Moreover, the argument presented in Section 2, part (ii) on the estimation of structural covariances may be readily extended to show that it is possible to estimate

\[(18) \quad \sigma_{11}^* = \sigma_{11}/\omega_{11}, \quad \sigma_{12}^* = \sigma_{12}^* \omega_{11}^{-1} = \frac{\sigma_{12}}{(\omega_{11} \omega_{22})^{1/2}},\]

and

\[\sigma_{22}^* = \frac{\sigma_{22}}{\omega_{22}}.\]

This completes the analysis of parameter identification.

The analysis of the full information maximum likelihood estimators is straightforward and need not be belabored. The likelihood function is

\[\mathcal{L} = \prod_{i=1}^{I} \left[ P_{00}(i) \right]^{(1-d_i)(1-a_i)} \left[ P_{01}(i) \right]^{(1-d_i)a_i} \left[ P_{10}(i) \right]^{d_i(1-a_i)} \left[ P_{11}(i) \right]^{a_i d_i}.\]

The function may be maximized with respect to the parameters listed in equations (17) and (18). As in the hybrid model, in a finite sample there is some probability that maximum likelihood estimators fail to exist but this probability becomes arbitrarily small as sample size becomes arbitrarily large. The maximum likelihood estimators are consistent, asymptotically normal, and efficient.\(^{22}\)

4. THE FORMULATION OF SIMULTANEOUS EQUATION MODELS WITH DISCRETE ENDOGENOUS VARIABLES\(^{23}\)

In this section, the models developed in this paper are contrasted with previous work on discrete models with jointly endogenous variables by Goodman [7] and Nerlove and Press [22]. These models deal with purely discrete variables. Accordingly, the appropriate comparison is one between that work and the models of Section 3 although an important topic is the issue of generalizing purely discrete models to accommodate both discrete and continuous endogenous variables.

It is argued here that the log linear model of Goodman and Nerlove and Press is a less than adequate scheme for formulating the simultaneous equation model required in econometrics. This is so for two reasons. The principal reason is that the log linear model is not sufficiently rich in parameters to distinguish structural association among discrete random variables from purely statistical association among discrete random variables. The distinction between structural and statistical association is at the heart of simultaneous equation theory. The second reason is that the log linear model does not readily generalize to accommodate continuous endogenous variables while the multivariate normal structure can easily be modified to do so, as has been demonstrated in previous sections of this

\(^{22}\) The same sort of existence conditions are required as those presented in Section 2. With probability one, maximum likelihood estimators exist in large samples.

\(^{23}\) I have greatly benefited from discussions with Marc Nerlove on the material in this section.
paper. Since the second reason is much discussed in the literature (see, e.g., Feinberg [6]) no further elaboration of this point is required here. The first reason does require some discussion.

To fix ideas, consider a log linear model for a two equation system comparable to the model of Section 3. Nerlove and Press [22, p. 51] explicitly consider a log linear model for this case. Altering their notation to conform with the notation of Section 3 and suppressing subscript \( i \), the log linear analogue of equations (16a)–(16d) is

\[
\begin{align*}
\ln \text{prob} (a = 0 \land d = 0) &= \ln P_{00} = \alpha_0 + \alpha_1 + \beta + \mu, \\
\ln \text{prob} (a = 0 \land d = 1) &= \ln P_{01} = \alpha_0 - \alpha_1 - \beta + \mu, \\
\ln \text{prob} (a = 1 \land d = 0) &= \ln P_{10} = -\alpha_0 + \alpha_1 - \beta + \mu, \\
\ln \text{prob} (a = 1 \land d = 1) &= \ln P_{11} = -\alpha_0 - \alpha_1 + \beta + \mu,
\end{align*}
\]

where \( \mu = -\ln [\exp (\alpha_0 + \alpha_1 + \beta) + \exp (\alpha_0 - \alpha_1 - \beta) + \exp (-\alpha_0 + \alpha_1 - \beta) + \exp (-\alpha_0 - \alpha_1 + \beta)] \) and \( \alpha_0, \alpha_1, \) and \( \beta \) may be parameterized as functions of exogenous variables.

The marginal probability of the event \( a = 0 \) in the log linear model is

\[
\text{prob} (a = 0) = \frac{\exp (\alpha_0 + \alpha_1 + \beta) + \exp (\alpha_0 - \alpha_1 - \beta)}{\exp (-\mu)}.
\]

This expression is to be compared with the corresponding probability given in Section 3 for the normal model with structural shift:

\[
\text{prob} (a = 0) = \sum_{d=0,1} [F(b - \pi_{13}^* d, -c, e)]^d [F(b - \pi_{13}^* d, c, -\rho)]^{1-d}.
\]

When \( \beta = 0 \), the log linear probability model collapses to a simple logit model

\[
\text{prob} (a = 0) = \frac{1}{1 + e^{-2\alpha_0}}.
\]

With \( \rho = 0 \), the normal model becomes a probit model with structural shift:

\[
\text{prob} (a = 0) = \sum_{d=0,1} [\Phi(b - \pi_{13}^* d)\Phi(-c)]^d [\Phi(b)\Phi(c)]^{1-d},
\]

where \( \Phi(t) \) is the standard univariate cumulative density \( = F(\infty, t, \rho) \). Finally, note that if there is no structural shift \( (\pi_{13}^* = 0) \), as well as no covariance \( (\rho = 0) \),

\[
\text{prob} (a = 0) = \Phi(b)
\]

so that a simple probit model arises.

Further note that in the log linear model, the conditional probability that \( a = 0 \) given \( d \) may be written as

\[
\text{prob} (a = 0|d) = \frac{1}{1 + e^{-2\alpha_0}} e^{(2\beta d - 2\beta(1-d))}.
\]
The simplicity of this representation is the basis for the popularity of the log linear model. The comparable expression for the normal model is

\[
\text{prob} (a = 0 | d) = \left( \frac{F(b - \pi_{13}^* d, -c, \rho)}{F(\infty, -c, \rho)} \right)^d \cdot \left( \frac{F(b - \pi_{13}^* d, c, -\rho)}{F(\infty, c, -\rho)} \right)^{1-d}.
\]

Note that \(\alpha_0\) and \(b, \alpha_1\) and \(c\) play similar roles in the model in which they appear. The important point to note, however, is that \(\beta\) and \(\rho\) and \(\pi_{13}^*\) play similar roles. In the normal model the probability that \(a = 0\) given \(d\) depends on \(d\) for two conceptually distinct reasons: one related to the true structure of the model \((\pi_{13}^* \neq 0)\) and the other due to covariance in latent errors \((\rho \neq 0)\). In the log linear model, these effects are indistinguishable. Thus the log linear parameter of association, \(\beta\), corresponds to two distinct parameters in the normal model \(\rho\) and \(\pi_{13}^*\).

As long as one only seeks to estimate empirical relationships among endogenous variables, this issue may be ignored. Suppose, however, that one seeks to utilize fitted econometric relationships to answer policy questions. Then, as Haavelmo [9] has stressed, it is important to identify structural parameters. A simple example will fix ideas.

Let \(a = 1\) if a family has a child and let \(a = 0\) if it does not. Let \(d = 1\) if the family uses birth control and \(d = 0\) otherwise. It may happen that because of unmeasured taste and knowledge factors, families more likely to contracept are more likely not to have a child. This effect would be captured in a normal model by setting values of the parameter \(\rho < 0\). There is, however, a second effect. For obvious structural reasons families on birth control will have fewer children \((\pi_{13}^* < 0\) in the normal model). For either reason \(\beta < 0\) in the log linear model.

Suppose that the government forces all families to contracept. The normal model would permit identification of the effect of this policy shift through use of \(\pi_{13}^*\). Thus the predicted change in the probability of a couple having no children as a result of the policy would be derived from equation (20) as

\[
\Delta P(a = 0) = \sum_{d=0,1} [F(b - \pi_{13}^*, -c, \rho)]^d [F(b - \pi_{13}^*, c, -\rho)]^{1-d} - \sum_{d=0,1} [F(b - d\pi_{13}^*, -c, \rho)]^d [F(b - d\pi_{13}^*, c, -\rho)]^{1-d}. 24
\]

Notice that if \(\pi_{13}^* = 0\), there would be no effect predicted for the policy, whether or not \(\rho = 0\).

The estimate of the policy effect from the log linear model would be given by subtracting the conditional probability that \(a = 0\) given \(d = 1\) (given in equation (21)) from the marginal probability (given in equation (19)),

\[
\Delta P = \text{prob} (a = 0 | d = 1) - \text{prob} (a = 0).
\]

24 The difference between the first term and the second term is that \(d\) is set to one inside the first term signifying that everyone in the population is forced to use birth control.
Since it is not possible to disentangle purely statistical association from purely causal association in the log linear model, it is not possible to identify meaningful structural parameters interpretable within the classical simultaneous equation framework. If one were to follow Amemiya’s [2] suggestion and use the log linear model to approximate a multivariate normal model, misleading predictions of policy effects might occur. Indeed, if \( \pi_{13}^* = 0 \), but \( \rho < 0 \) in the normal model, the log linear model would predict an effect of the program (\( \beta < 0 \)) even when none in fact would occur. Conversely, if \( \pi_{13}^* > 0 \) and \( \rho < 0 \), estimated independence of events in the log linear model (\( \beta = 0 \)) would lead to incorrect forecasts of policy effects. Note, however, that if dummy variables are defined as indicators of latent variables that cross thresholds, and not as structural shift parameters (\( \pi_{13}^* = 0 \)), Amemiya’s suggestion is appropriate, and the log linear model may be used to approximate a multivariate normal model. The parameters \( \beta \) and \( \rho \) then play similar roles in their respective models. Alternatively, if it is assumed that there is no correlation among the disturbances generating the continuous latent variables in the normal model (\( \rho = 0 \), while structural shift is permitted (\( \pi_{13}^* \neq 0 \)), the parameters \( \beta \) and \( \pi_{13}^* \) again play similar roles in their respective models.

It is important to note that the differences between the two models are more profound than this comparison may suggest. Although Nerlove and Press [22] note that log linear probabilities are intimately related to a cumulative multivariate logistic distribution, it is misleading to think that the cumulative logistic distribution plays the same role as the multivariate normal distribution plays in the model of Sections 2 and 3 of this paper. The transition from the multivariate normal model to the log linear model involves more than a convenient choice of a joint distribution for the latent variables introduced in Section 1 of this paper. Indeed, if one were to use the multivariate logistic model discussed by Nerlove and Press as a replacement for the multivariate normal model in the analysis of Section 3 of this paper, another model would not derive a log linear model, but yet another model (the multivariate logit model?) that would be similar to the multivariate probit model previously discussed in the sense that the parameters of one model would exactly correspond to the parameters of the other.

\[ F(Y_1, \ldots, Y_n) = \frac{1}{1 + \sum_{i=1}^{n} \exp(-Y_i)} \]

\[ 25 \] Indeed, Amemiya’s suggestion is clearly intended for a multivariate probit model with dummy variables defined in this way. See Amemiya [2].

\[ 26 \] The multivariate logistic model employed by Nerlove and Press is the cumulative distribution

\[ 27 \] A full discussion of this new model is beyond the scope of this paper. Still, it is worth noting that the proposed multivariate logit model would be inadequate because the corresponding value of \( \rho \) would be arbitrarily set at \( \frac{1}{2} \). See Gumbel [8] or Johnson and Kotz [13, p. 293]. A better multivariate logit model would be based on Gumbel’s “second bivariate logistic distribution” (Gumbel [8]). This distribution is flexible enough to permit any arbitrary correlation among latent logit variables. An extension of Gumbel’s “second model” to a multivariate model would provide the basis for a multivariate logit model with structural shift that would be fully comparable with the model developed in Section 3 of this paper, and which could be used as a framework for generating the model of Section 2 as well. A full development of this new model would be fascinating but requires another paper.
The log linear model is a very flexible tool for approximating any joint
distribution of discrete endogenous variables as long as a precise structural
model is not required. Because conditional probability statements are so easily
calculated within this framework, the log linear model is an invaluable aid for
investigating empirical relationships among discrete endogenous variables.

The normal models developed in this paper permit a precise structural inter-
pretation of relationships among discrete endogenous variables. These models
are sufficiently flexible to encompass random utility models (see footnote 28)
and simultaneous equation models with both discrete and continuous endo-
genous variables. For these reasons, the models proposed in this paper are more
general and more flexible than the log linear model.

SUMMARY

This paper develops a class of econometric models for simultaneous equation
systems with dummy endogenous variables. These models are based on the
pioneering work of Pearson [25] on dichotomized variables. The general model
presented here includes simultaneous probit and ordinary simultaneous equa-
tion models as special cases. Dummy endogenous variables are introduced in
two conceptually distinct roles: (1) as proxy variables for unmeasured latent
variables crossing thresholds, as in the classical quantal response model (Ame-
miya, [2]) and (2) as direct shifters of structural behavioral equations formulated
in terms of latent variables. This distinction is shown to be quite important in the
formulation and interpretation of the econometric models developed here.
Maximum likelihood and alternative estimators are discussed. Conditions for the
existence of a meaningful statistical model are derived.

The log linear model can be given a structural interpretation. McFadden [20, p. 379] has
recently demonstrated that a special case of the log linear model arises from a random utility model
with interactions in utility among different types of choices. This model closely resembles the
multivariate probit model with structural shift and without correlation among latent variables
(ρ = 0), because no covariance is permitted among the random variables associated with the utility of
each possible choice. For this reason such a model is quite restrictive, and is unlikely to have much
appeal in applied work.

It is useful to note in this context that the multivariate probit introduced in Section 3 of this paper
may be used to characterize a random utility model. Thus the framework of McFadden [20] can be
incorporated within the “threshold models” advanced in this paper.

To illustrate this point, suppose that a consumer has J choices with associated utilities $U_j$, $j = 1, \ldots, J$. The probability that choice i is made is the probability that $U_j$ is maximal in the set
{$U_j$}$i=1$. Define random variables $z_{ik} = U_j - U_k$, $l < k$, $l, k = 1, \ldots, J$, and let $d_{lk} = 1$ iff $z_{lk} \geq 0$ while
$d_{lk} = 0$ otherwise. If $z_{ik}$ is normally distributed, the distribution of random variables $d_{ik}$ generated
from the dichotomization of $z_{ik}$ is a $J(J-1)/2$ variate cumulative multivariate normal representing
the distribution of all two way utility comparisons. The probability that i is selected is a $J-1$ variate
multivariate probit obtained from the $J(J-1)/2$ variate probit by summing out random variables $d_{ik}$, $l \neq i$, and may be written as $pr (d_{i1} = 0, \ldots, d_{ij} = 0 | d_{i1} = 1, \ldots, d_{ij} = 1)$. Thus the threshold
model nests the random utility model within it as a special case. Clearly if data on irrelevant utility
comparisons were available, they could be used to improve the precision of the estimates of the
model.

Note that estimators of conditional probabilities in the log linear model have the same
interpretation as direct least squares estimators in classical simultaneous equation theory which are
also estimators of conditional probability statements. Both estimators of their respective models
produce estimates that confound true structural parameters with elements of the equation error
covariance structure.
The models presented here have already been put to practical use (see Edwards [5] and Heckman [11, 12]). They are computationally tractable and in the applications cited have led to new interpretations of old evidence.

The models formulated here are compared with alternative models by Goodman [7] and Nerlove and Press [22]. It is shown that the log linear model does not provide a natural framework for formulating the simultaneous equation model of econometrics whereas the models presented in this paper do.

APPENDIX A

DERIVATION OF THE DENSITY \( f(y_{1t}, d_t) \)

In this appendix, there is a brief discussion of the derivation of density \( f(y_{1t}, d_t) \) that is used in the text. This discussion is useful because random variables that are the sum of underlying continuous and discrete random variables are unfamiliar in econometrics. The joint density of \( V_{1t}, V^*_{21} (= V_{2t}/\sigma_{12}^2) \) is given by \( h(V_{1t}, V^*_{21}) \), a bivariate normal density. The joint density of \( V_{1t} \) and \( d_t \) is

\[
e(V_{1t}, d_t) = \left[ \int_{-\infty}^{\infty} h(V_{1t}, V^*_{21}) dV^*_{21} \right]^{1/2} \left[ \int_{-\infty}^{\infty} h(V_{1t}, V^*_{21}) dV^*_{21} \right]^{1-d_t}
\]

where \( c_t = -(X_{1t}, \pi^*_t + X_{2t}, \pi^*_t, \pi^*_t) \).

Define a random variable \( Z_t = V_{1t} + \pi_{13} d_t \). The joint density of \( Z_t, d_t \) is simply

\[
e(Z_t - \pi_{13} d_t, d_t) = \left[ \int_{-\infty}^{\infty} h(Z_t - \pi_{13} d_t, V^*_{21}) dV^*_{21} \right]^{1/2} \left[ \int_{-\infty}^{\infty} h(Z_t - \pi_{13} d_t, V^*_{21}) dV^*_{21} \right]^{1-d_t}
\]

Substitute \( y_{1t} - X_{1t} \pi_{11} - X_{2t} \pi_{12} \) for \( Z_t \) (noting that the Jacobian is unity) to reach the density \( f(y_{1t}, d_t) \) used in the text.

The marginal density for \( Z_t \) is

\[
e_1(Z_t) = \left[ \int_{-\infty}^{\infty} h(Z_t - \pi_{13}, V^*_{21}) dV^*_{21} \right]^{1/2} \left[ \int_{-\infty}^{\infty} h(Z_t, V^*_{21}) dV^*_{21} \right]^{1-d_t}
\]

Using conditional normal theory one can write

\[
h(Z_t - \pi_{13}, V^*_{21}) = \phi(Z_t - \pi_{13} | V^*_{21}) h_2(V^*_{21})
\]

and, also, clearly

\[
h(Z_t, V^*_{21}) = \phi(Z_t | V^*_{21}) h_2(V^*_{21})
\]

where \( \phi(\cdot) \) is a conditional normal density. Then obviously \( e_1(Z_t) \) is a proper density since

\[
\int_{-\infty}^{\infty} e_1(Z_t) dZ_t = \int_{-\infty}^{C_t} \int_{-\infty}^{\infty} \phi(Z_t | V^*_{21}) h_2(V^*_{21}) dZ_t dV^*_{21}
\]

\[
+ \int_{C_t}^{\infty} \int_{-\infty}^{\infty} \phi(Z_t - \pi_{13} | V^*_{21}) h_2(V^*_{21}) dZ_t dV^*_{21}
\]

\[
= 1
\]

since \( \int_{-\infty}^{\infty} \phi(Z_t | V^*_{21}) dZ_t = 1 \).
Multivariate extensions of the models of Sections 2 and 3 in the text are presented in this appendix. Let $Y_i^+$ be a row vector of $G$ jointly endogenous latent random variables, some of which may be observed. Let $l$ be a $G \times G$ nonsingular matrix with unit diagonal elements. $X_i$ is a $1 \times K$ row vector of bounded exogenous variables. $A$ is a $K \times G$ coefficient matrix for the exogenous variables. "$d_i$" is a $1 \times C$ vector of dummy variables ($C \ll G$). Only $C_1 (\ll C)$ of these dummy variables act as shifters of the structural equations. Associated with the $C_1$ shift dummy variables is a $C_1 \times G$ coefficient matrix $B$. $U_i$ is a $1 \times G$ vector of disturbances for observation $i$, $i = 1, \ldots, I$.

The structural equation system may be written as

$$Y_i^+ = X_i \Gamma + d_i A + d_i B = U_i$$

where

$$E(U_i) = 0, \quad E(U_i' U_i) = \Sigma,$$

and

$$E(U_i' U_j) = 0, \quad i \neq j.$$

$U_i$ is assumed to be a multivariate normal random vector. $\Sigma$ is positive definite. For notational convenience, suppose that the first $C$ latent variables activate the $C$ dummy variables,

$$d_{ij} = 1, \quad \text{iff} \quad Y_{ij}^+ \geq 0,$$

$$d_{ij} = 0 \quad \text{otherwise}, \quad j = 1, \ldots, C,$$

and that the first $C$ variables in $Y_i^+$ are unobserved while the remaining $G - C$ variables are observed.\footnote{Note that case 2 in Section 1 of the text is excluded by the assumption that $C_1 < C$ and that only unobserved latent variables generate structural shift. The model can readily be generalized to include this case.}

Finally, note that $C \gg C_1$, and assume that the first $C_1$ latent variables generate the $C_1$ shift dummies.

The semi-reduced form for the system is

$$Y_i^* = X_i \pi + d_i \tilde{\pi} + V_i$$

where

$$\pi = -A \Gamma^{-1}, \quad \tilde{\pi} = -B \Gamma^{-1}, \quad \text{and} \quad V_i = U_i \Gamma^{-1}.$$

It is convenient to work with reduced form variance normalized versions of these coefficients. Define $\Omega$ as

$$\Omega = E(V_i' V_i) = (\Gamma^{-1})' \Sigma \Gamma^{-1}. \quad \text{Diagonal matrix} \ D \text{ is defined by}$$

$$D^2 = \text{diag} \ \Omega.$$

$D$ displays the population standard deviation for each element of $V_i$. Partition $D$, and define $D^*$ as

$$D^* = \begin{pmatrix} D_C & 0 \\ 0 & I_{G-C} \end{pmatrix}$$

where $D_C$ is a $C \times C$ submatrix of the first $C$ diagonal elements of $D$, and $I_{G-C}$ is a $(G-C) \times (G-C)$ identity matrix.

Postmultiply equation (B-2) by $(D^*)^{-1}$ to reach

$$Y_i^{**} = X_i \pi^* + d_i \tilde{\pi}^* + V_i^*,$$

$$E[(V_i^*') V_i^*] = \Omega^* = (D^*)^{-1} \Omega (D^*)^{-1}.$$
This operation normalizes the first \( C \) semi-reduced form equations to have a unit variance disturbance, an obvious generalization of the procedure utilized in Section 2 in the text. Note that

\[
\pi^* = \pi(D^*)^{-1}, \quad \tilde{\pi}^* = \tilde{\pi}(D^*)^{-1}.
\]

In the notation of this appendix, the principal assumption in the text requires that through a permutation of the indices of the latent variables, the first \( C \) columns and rows of \( \pi^* \) can be brought into a lower triangular matrix with zero diagonal elements. Thus the principal assumption becomes (in the suitably permuted indices)

\[
\tilde{\pi}^*_{ij} = 0, \quad j > i; \quad i, j = 1, \ldots, C_1.
\]

This condition is both necessary and sufficient for the existence of a meaningful statistical model. Assuming that the reduced form model is of full rank, coefficients in the first \( C \) columns of \( \pi^* \) may be estimated by applying probit analysis and the conditional estimator discussed in Section 3 in seriatim to each equation. If \( C > C_1 \), the coefficients in the next \( C - C_1 \) columns of \( \pi^* \) and \( \tilde{\pi}^* \) may be estimated by applying the methods of Section 3 to each equation. Assuming \( G > C \), the coefficients of the final \( G - C \) columns of \( \pi^* \) and \( \tilde{\pi}^* \) may be consistently estimated by applying the methods of Section 2 to each equation. Precisely the same type of argument offered in Section 2 establishes that all elements of \( \Omega^* \) are estimable.

Now consider the estimation of structural coefficients. Assume that through exclusion restrictions all nonzero coefficients in equation (B-1) could be identified if \( Y_t^* \) were observable.\(^{31}\) Clearly, in the transition to equation system (B-1) with some continuous variables unobserved, the same regression coefficients that can be identified in the previous case can be identified in the current model if they are suitably renormalized. To obtain the required normalization, rewrite equation (B-1) in terms of normalized latent variables

(B-1) \[ Y_t^* (D^*)^{-1} D^* \Gamma + X_t A \theta + d_t B = U_t. \]

For the normalization implicit in the choice of \( \Gamma \), it is natural to postmultiply this equation by \((D^*)^{-1}\) to reach

(B-1') \[ (Y_t^* (D^*)^{-1})(D^* \Gamma (D^*)^{-1}) + X_t A (D^*)^{-1} + d_t B (D^*)^{-1} = U_t (D^*)^{-1}. \]

Clearly, then, one can identify the following parameters:

(B-4) \[ \Gamma^* = D^* \Gamma (D^*)^{-1}, \quad A^* = A (D^*)^{-1}, \quad B^* = B (D^*)^{-1}. \]

Finally, it is clear that one can identify the following parameters of the structural covariance terms

(B-5) \[ \Sigma^* = (D^*)^{-1} \Sigma (D^*)^{-1}. \]

This completes the analysis of parameter identification.

The likelihood function for the model may be generated from the density for random variables \( d_t \) and \( Y_t^* \) where \( Y_t^* \) is the \( 1 \times (G - C) \) subvector of \( Y_t^* \) corresponding to the observed continuous variables. That density is defined next. Let \( \psi_i \) be defined as

\[ \psi_i = X_t \pi^* + d_t \pi^*. \]

Partition \( \psi_i \) into \( \psi_i,_{C} \) and \( \psi_i,_{G-C} \), i.e., \( \psi_i = (\psi_i,_{C}, \psi_i,_{G-C}) \). Then the density for \( d_t, \ Y_t^* \), \( g(d_t, \ Y_t^*) \) is given by

\[ g(d_t, \ Y_t^*) = F_2(\psi_{i,_{C}}[2d_t - \iota], \ Y_t^* - \psi_{i,_{G-C}}; \Sigma^* [2d_t - \iota] [2d_t - \iota]^t) \]

where * denotes a Hadamard product, \( \iota \) is a \( 1 \times C \) vector of "1's," and 2 is the number "2." \( F_2 \) is the derivative of the cumulative distribution for the multivariate normal with respect to the final \( G - C \) elements of \( U_t^* = U_t (D^*)^{-1} \), i.e.,

\[ F_2(U_t^*; \Sigma^*) \propto \prod_{i=1}^{d_t} [\Sigma^*]^{-1/2} \exp \left[ -\frac{1}{2} (U_t^* (\Sigma^*)^{-1} U_t^*) \right] du_{iC} \]

where \( U_t^* = (U_{iC}, U_{i,G-C}). \)

The sample likelihood function is

\[ \mathcal{L} = \prod_{i=1}^{T} g(d_t, \ Y_t^*) \]

\(^{31}\) The restriction to exclusion restrictions is overly stringent. Identification through use of covariance restrictions is also permitted so long as such restrictions can be imposed on \( \Omega^* \).
which is to be maximized with respect to the terms in equations (B-4) and (B-5). As in the text, the identification analysis produces initial consistent estimators to use as starting values. In large samples, maximum likelihood estimators exist, and are consistent and asymptotically efficient.

One final multivariate extension is worth noting. The models developed thus far are for unordered dichotomous variables. In some cases, dummy endogenous variables may be naturally ordered. For example, in an analysis of the effects of legislation on the income of blacks, one might distinguish existing laws by their “strength” and a natural ordering would exist. One simple way to generate such ordered dichotomies is to polytomize a single latent continuous random variable. Thus, each element of \( d_n \), say \( d_{nc} \), might be replaced by a vector of dummy variables, with a typical element \( d_{ncj} \) defined as

\[
d_{ncj} = \begin{cases} 1 & \text{iff } \phi_{j-1} < Y_{nc}^* < \phi_j, \\ 0 & \text{otherwise}, \end{cases} \quad j = 1, \ldots, J_c,
\]

where the categories are mutually exclusive, and the \( \phi_j \), \( j = 1, J_c \) are a set of estimable constants (fixing \( \phi_0 = -\infty \) and \( \phi_{J_c} = \infty \)).

Each of the \( C \) dummy variables may be polytomized in this fashion.\(^{32}\)

REFERENCES

\(^{32}\) This procedure for generating ordered dichotomous variables is discussed in more specialized cases by Johnson [14] and Amemiya [2].
