## Abstract

This paper estimates the rate of return to the High/Scope Perry Preschool Program, an early intervention program targeted toward disadvantaged African-American youth. Estimates of the rate of return to the Perry program are widely cited to support the claim of substantial economic benefits from preschool educational programs. Previous studies of the rate of return to this program ignore the compromises that occurred in the Perry randomization protocol. They do not report standard errors or conduct systematic sensitivity analyses that account for components of costs and benefits that cannot be assigned a standard error because they involve judgements about aspects of costs and benefits. Previous studies also ignore the deadweight costs of

taxation. The rates of return estimated in this paper account for these factors. Social rates of return generally range between 7–10 percent, with most estimated returns substantially lower than those previously reported in the literature. However, returns are generally statistically significantly different from zero for both males and females and are comparable to the historical return on equity. The estimated benefit-to-cost ratios generally support this conclusion.

*Key words:* rate of return, cost-benefit analysis, standard errors, Perry Preschool Program, compromised randomization, early childhood intervention programs, deadweight costs

## 1. Introduction

President Barack Obama has strongly promoted early childhood education as a way to foster economic efficiency and to reduce inequality.<sup>5</sup> He has also endorsed accountability and transparency in government.<sup>6</sup> In an era of tight budgets and fiscal austerity, it is important to prioritize expenditure and use funds wisely. As the size of government expands, there is a renewed demand for cost-benefit analyses to weed out political pork from economically productive programs.<sup>7</sup>

The economic case for expanding preschool education for disadvantaged

<sup>5</sup>See Dillon (2008).

<sup>6</sup>Weekly address of the President, January 31, 2009, as cited in Bajaj and Labaton (2009).

<sup>7</sup>The McArthur Foundation has recently launched an initiative to promote the application of cost-benefit analysis in the service of making government effective. See Fanton (2008).

children is largely based on evidence from the Perry Preschool Program, an early intervention in the lives of disadvantaged children in the early 1960s.<sup>8</sup> In that program, children were randomly assigned to treatment and control group status and have been systematically followed through age 40. Information on earnings, employment, education, crime and a variety of other outcomes are collected at various ages of the study participants. In a highly cited paper, Rolnick and Grunewald (2003) estimate a rate of return of 16 percent to the Perry Program. Belfield et al. (2006) report a 17 percent rate of return.

Critics of the Perry Preschool Program point to the small sample size of the evaluation study (123 preschool participants and controls), the lack of a substantial long-term effect of the program on IQ, and the absence of statistical significance for many estimated treatment effects.<sup>9</sup> Hanushek and Lindseth (2009) question the strength of the evidence on the Perry Program, claiming that estimates of its impact are fragile.

The literature does little to assuage these concerns. All of the reported estimates of rates of return are presented without standard errors, leaving readers uncertain as to whether the estimates are statistically significantly different from zero. The paper by Rolnick and Grunewald (2003) reports few details and no sensitivity analyses to alternative assumptions about costs and benefits of key public programs and of the costs of crime. The study

---

<sup>8</sup>See, e.g., Shonkoff and Phillips (2000) or Karoly et al. (2005). No other early childhood intervention has a follow-up into adult life as late as the Perry Program. For example, the benefit-cost study of the Abecedarian Program only follows people to age 21, and relies heavily on extrapolation of future earnings (Barnett and Masse, 2007).

<sup>9</sup>See Herrnstein and Murray (1994, pp.404-405).

by Belfield et al. (2006) also does not report standard errors. It provides more details on how the estimates are obtained, but conducts only a limited sensitivity analysis.

Any computation of the lifetime rate of return to the Perry Program must address four major challenges: (a) the randomization protocol was compromised, (b) the lack of any data past age 40 and the need to extrapolate out-of-sample to obtain earnings profiles past that age to estimate lifetime impacts of the program, (c) missing data for participants prior to age 40, and (d) the difficulty in assigning reliable values to non-market outcomes such as crime. The last point is especially relevant to any analysis of the Perry program because crime reduction is one of its major benefits. Unless these points are systematically addressed, the true rate of return remains uncertain as does the economic case for early intervention.

This paper presents rigorous estimates of the rate of return and the benefit-cost ratio for the Perry Program. Our analysis improves on previous studies in seven ways. (1) We account for compromised randomization in evaluating this program. As noted in Heckman, Moon, Pinto, Savelyev, and Yavitz (2009), in the Perry study, the randomization actually implemented in this program is somewhat problematic because of reassignment of treatment and control status *after* random assignment. (2) We develop standard errors for all of our estimates of the rate of return and for the benefit-to-cost ratios accounting for components of the model where standard errors can be reliably determined. (3) For the remaining components of costs and benefits where meaningful standard errors cannot be determined, we examine the sensitivity of estimates of rates of return to plausible ranges of assumptions. (4) We

present estimates that adjust for the deadweight costs of taxation. Previous estimates ignore the costs of raising taxes in financing programs. (5) We use a much wider variety of methods to impute within-sample missing earnings than have been used in the previous literature, and examine the sensitivity of our estimates to the application of alternative imputation procedures that draw on standard methods in the literature on panel data.<sup>10</sup> (6) We use state-of-the-art methods to extrapolate missing future earnings for both treatment and control group participants. We examine the sensitivity of our estimates to plausible alternative assumptions about out-of-sample earnings. We also report estimates to age 40 that do not require extrapolation. (7) We use local data on costs of education, crime, and welfare participation whenever possible, instead of following earlier studies in using national data for these components of the rate of return.

Table 1 summarizes the range of estimates from our preferred methodology, defended later in this paper. Results from a diverse set of methodologies can be found from Web Appendix J. All point in the same direction. Separate rates of return are reported for benefits accruing to individuals in the form of higher earnings and for benefits to society at large that include the impact of the program on crime, participation in welfare, and the resulting savings in social costs. Our estimate of the overall social rate of return to the Perry Preschool Program is in the range of 7–10 percent. We report a range of estimates because of uncertainty about certain components of benefits and costs that cannot be quantified by a standard error. Our estimates of the

---

<sup>10</sup>See, *e.g.*, MaCurdy (2007) for a survey of these methods.

return are comparable to estimates on the return to equity.<sup>11</sup> However, they are generally substantially below the estimates of the rate of return to the Perry Program that are reported in previous studies. The benefit-to-cost ratios presented in the bottom of Table 1 support this conclusion. The rest of the paper justifies the estimates presented in Table 1.

The paper proceeds in the following way. Section 2 discusses the Perry Preschool Program and how it was evaluated. It discusses compromises in the randomization protocol that was implemented. Section 3 discusses the sampling plan used to collect the outcomes of the experiment and the empirical problems it creates, which require imputation and extrapolation to compute the rate of return. Problems of estimating non-market benefits of the program are discussed. Section 4 presents our estimates and their sensitivity to alternative plausible assumptions. We contrast our approach with the approaches taken by other analysts. In the final section, we summarize our findings and draw conclusions.

## **2. Perry: Experimental Design and Background**

The High/Scope Perry Preschool Program was an early childhood education program conducted at the Perry Elementary School in Ypsilanti, Michigan, during the early 1960s. Beginning at age three and lasting two years, treatment consisted of a 2.5-hour preschool program on weekdays during the

---

<sup>11</sup>The estimated mean returns are above the post-World War II stock market rate of return on equity of 5.8 percent (see DeLong and Magin, 2009).

Internal Rates of Return

Benefit-Cost Ratios

**Notes:** : Kernel matching is used to impute missing values for earnings before age-40, and PSID projection for extrapolation of later earnings. For details of these procedures, see Section 3. In calculating benefit-to-cost ratios, the deadweight loss of taxation is assumed to be 50%. Standard errors in parentheses are calculated by Monte Carlo resampling of prediction errors and bootstrapping; see Web Appendix K for details. (a) A ratio of victimization rate (from the NCVS) to arrest rate (from the Uniform Crime Report), where “Prop. / Violent” uses common ratios based on a crime being either violent or property and “Separate” does not; (b) “high” murder cost accounts for statistical value of life, while “low” does not; (c) Deadweight cost is dollars of welfare loss per tax dollar; (d) The sum of returns to program participants and the general public; (e) “All” is computed from an average of the profiles of the pooled sample, and may be lower or higher than the profiles for each gender group; (f) Lifetime net benefit streams are adjusted for corrupted randomization. For details, see Section 4.

school year, supplemented by weekly home visits by teachers.

The curriculum was based on supporting children’s cognitive and socio-emotional development through *active learning* where both teachers and children had major roles in shaping children’s learning. Children were encouraged to plan, carry out, and reflect on their own activities through a plan-do-review process. Adults observed, supported, and extended children’s play as appropriate. They also encouraged children to make choices, problem solve, and engage in activities. Instead of providing lessons, Perry emphasized reflective and open-ended questions asked by teachers. Examples are: “What happened? How did you make that? Can you show me? Can you help another child?” (Schweinhart, Barnes, and Weikart, 1993, p. 33).<sup>12</sup>

*Eligibility Criteria.* Five cohorts of preschoolers were enrolled in the program in the early to the mid-1960’s. Drawn from the community served by the Perry Elementary School, participants were located through a survey of families associated with that school, as well as through neighborhood group referrals, and door-to-door canvassing. Disadvantaged children living in adverse circumstances were identified using IQ scores and a family socioeconomic status (SES) index. Those with IQ scores outside the range of 70-85 were excluded, as were those with mental defects who could not be treated with the available technology.

---

<sup>12</sup>Web Appendix A provides further information on the program. See <http://jenni.uchicago.edu/Perry/cba/>.

*The Compromised Randomization Protocol.* A potential problem with the Perry study is that after random assignment, treatment and controls were reassigned, compromising the original random assignment and making simple interpretation of the evidence problematic. In addition, there was some imbalance in the baseline variables between treatment and control groups. Heckman, Moon, Pinto, Savelyev, and Yavitz (2009) discuss the Perry selection and randomization protocols in detail. They correct for the imbalance in preprogram variables and the compromise in randomization using matching. We use their procedures in this analysis.

*Evidence on Selective Participation.* Weikart et al. (1978) claim that “virtually all” eligible families agreed to participate in the program, implying that there is no issue of bias arising from selective participation of more motivated families from the pool of eligible participants.<sup>13</sup>

*Study Follow-Up.* Follow-up interviews were conducted when participants were approximately 15, 19, 27, and 40 years old. Attrition remains low throughout the study, with over 90 percent of the original sample participating in the age-40 interview. At these interviews, participants provided detailed information about their lifecycle trajectories including schooling, economic activity, marital life, child rearing, incarceration, and other details. In addition, Perry researchers collect administrative data in the form

---

<sup>13</sup>Heckman, Moon, Pinto, Savelyev, and Yavitz (2009) discuss the external validity of the Perry study.

of school records, police and court records, and welfare program participation records.

*The Previous Literature and Its Critics.* As the oldest and most cited early childhood intervention, the Perry study serves as a flagship for policy makers advocating public support for early childhood programs. The High/Scope Foundation has collaborated with outside researchers to evaluate this program and released cost-benefit analyses associated with the age-27 and age-40 follow-up studies.<sup>14</sup> An independent study was conducted by Rolnick and Grunewald (2003). These studies report high internal rates of return (IRR): 16 percent by Rolnick and Grunewald (2003) and 17 percent by Belfield et al. (2006).

Our analysis challenges these estimates. Unlike the previous estimates, our estimated rates of return recognize the problems with the data and the problems raised by imbalances in preprogram variables between treatments and controls and by compromised randomization. The previous studies are unable to answer many important questions: How reliable are the IRR estimates? Can we conclude that the estimated IRRs are statistically significantly different from zero? Are all assumptions, accounting rules and estimation methods employed in previous studies reasonable? How would different plausible earnings imputation and extrapolation methods impact estimates of the IRR? If crime costs drive the IRR results, as some previ-

---

<sup>14</sup>Barnett (1996) and Belfield, Nores, Barnett, and Schweinhart (2006) respectively.

ous studies find, what are the consequences of estimating these costs under different assumptions?<sup>15</sup>

### 3. Program Costs and Benefits

The internal rate of return (IRR) is the annualized rate of return that equates the present values of costs and benefits between treatment and control group members. Lifetime benefits and costs through age 40 are directly measured using follow-up interviews. Extrapolation can be used to extend these profiles through age 65. Alternatively, we also compute rates of return through age 40. The scope of our evaluation is confined to the costs and benefits of education, earnings, criminal behavior, tax payments, and reliance on public welfare programs. There are no reliable data on health outcomes, marital and parental outcomes, the quality of social life and the like.<sup>16</sup> Hence, our estimated rate of return likely understates the true rate of return although we have no direct evidence on this issue. We present separate estimates of rates of return for private benefits and more inclusive social benefits.

#### 3.1. Initial Program Cost

We use the estimates of initial program costs presented in Barnett (1996). These include both operating costs (teacher salaries and administrative costs)

---

<sup>15</sup>Belfield et al. (2006) note the importance of crime in generating the estimated rate of return to the Perry program.

<sup>16</sup>Appendix B summarizes the data sources which we use in this paper.

and capital costs (classrooms and facilities). This information is summarized in Web Appendix C. In undiscounted year-2006 dollars, costs of the program per child are \$17,759.

### *3.2. Program Benefits: Education*

Perry promoted educational attainment through two avenues: total years of education attained and rates of progression to a given level of education. This pattern is particularly evident for females. Treated females received less special education, progressed more quickly through grades, earned higher GPAs, and attained higher levels of education than their control-group counterparts. The statistical significance of these differences depends on the methodology used, but all results point in the same direction. For males, however, the impact of the program on schooling attainment is weak at best.<sup>17</sup>

In this section, we report estimates of tuition and other pecuniary costs paid by individuals to regular K-12 educational institutions, colleges, and vocational training institutions, and additional social costs incurred by society to educate them.<sup>18</sup> The amount of educational expenditure that the general public spends will be larger if a person attains more schooling or if they progress through school less efficiently. Web Appendix D presents detailed

---

<sup>17</sup>This pattern was first noted in Heckman (2005). See also Anderson (2008) and Heckman, Moon, Pinto, Savelyev, and Yavitz (2009).

<sup>18</sup>All monetary values are in year-2006 dollars unless otherwise specified. Social costs include the additional funds beyond tuition paid required to educate students.

information on the statistics described in this section.

*K-12 Education.* To calculate the cost of K-12 education, we assume that all Perry subjects went to public school at the cost of annual per pupil expenditure in the state of Michigan during the period in question, \$6,645.<sup>19</sup> Treatment group members spent only slightly more time in the K-12 system, in spite of the discrepancy between treatment and control group graduation rates. Among females, control subjects were held back in school more often, equalizing the social cost of educating them in the K-12 system with that of the treatment group. Society spent comparable amounts of resources on individuals during their K-12 education regardless of their treatment experience, albeit for different reasons. Most treatment females who stayed longer obtained diplomas, while most control females who stayed longer repeated grades and many eventually dropped out. For males, educational experiences were very similar between treatments and controls.

*GED and Special Education.* Some male dropouts acquired high school certificates through GED testing. Our estimates of the private costs of K-12 education include the cost of getting a GED.<sup>20</sup> Female control subjects received more special education than treatment subjects. For males, there was

---

<sup>19</sup>“Total expenditure per pupil in public elementary and secondary education” for years 1974-1980, as reported by the Digest of Education Statistics (1975-1982, each year, in year-2006 dollars). We assume that public K-12 education entails no private cost for individuals. Detailed per pupil expenditures for Ypsilanti schools are not available for the relevant years.

<sup>20</sup>For detailed statistics about the GED, see Heckman and LaFontaine (2008).

no difference in receipt of special education by treatment status. Special services require additional spending. To calculate this cost, we use estimates from Chambers, Parrish, and Harr (2004), who provide a historical trend of the ratio of per-pupil costs for special and regular education.<sup>21</sup>

*2- and 4-Year Colleges.* To calculate the cost of college education, we use each individual’s record of credit hours attempted multiplied by the cost per credit hour (including both student-paid tuition costs and public institutional expenditures), taking into account the type of college attended.<sup>22</sup> Male control subjects attended more college classes than male treatment subjects — the reverse of the pattern for females. As a result, the social cost of college education is bigger for the control group among males while it is bigger for the treatment group among females.

After the age-27 interview, many Perry subjects progressed to higher education. Without having detailed information about educational attainment between the age-27 and age-40 interviews, we make some crude cost estimates. For college education, we assume “some college education” to be

---

<sup>21</sup>In 1968–69, this ratio was about 1.92; in 1977–78, it was 2.17. Since Perry subjects attended K-12 education in between these two periods, we simplify the ratio to 2 and apply it to all K-12 schooling years, which gives an additional \$6,645 annual per-pupil cost for special education.

<sup>22</sup>Total cost is the sum of private tuition and public expenditure. For student-paid tuition costs at a 2-year college, we use the 1985 tuition per credit hour for Washtenaw Community College (\$29); for a 4-year college, that of Michigan State University for the same year (\$42). To calculate public institutional expenditure per credit hour, we divide the national mean of total per-student annual expenditure (National Center for Education Statistics, 1991, “Expenditure per Full-Time-Equivalent Student”, Table 298) by 30, a typical credit-hour requirement for full-time students at U.S. colleges. This calculation yields \$590 per credit hour for 2-year colleges and \$1,765 for 4-year colleges.

equivalent to 1-year attendance at a 2-year college. For 2-year or 4-year college degrees, we take the tuition and expenditure estimates used for college going before age 27.<sup>23</sup> Without detailed information about whether a subject did or did not get any financial support, we assume that the private cost for a 2-year master's degree is the same as that for a 4-year bachelor's degree. Control males and treatment females pursued higher education more vigorously than did their same-sex counterparts, although only the treatment effect for females is statistically significant.

*Vocational Training.* Some subjects attended vocational training programs. Among males, control group members were more likely to attend vocational programs, although the treatment effect is not precisely determined. Among females, the pattern is reversed and the treatment effect is precisely determined. Thus, the public spent more resources to train control males and treatment females than their respective counterparts.<sup>24</sup> Individual costs are calculated using the number of months each Perry subject attended a vocational training institute. Table 2 summarizes the components of our estimated educational costs. The other components of costs and benefits are discussed later.

---

<sup>23</sup>For missing information on educational attainment, we use the corresponding gender-treatment group mean.

<sup>24</sup>We assume that all costs are paid by the general public. Estimates by Tsang (1997) suggest per-trainee costs which are 1.8 times the per-pupil costs of regular high school education.

Table 2: Summary of Lifetime Costs and Benefits (in undiscounted 2006 dollars)

	<b>Crime Ratio<sup>a</sup></b>	<b>Murder Cost<sup>b</sup></b>	<b>Male</b>		<b>Female</b>

**Notes:** (a) A ratio of victimization rate (from the NCVS) to arrest rate (from the Uniform Crime Report), where “by type” uses common ratios based on a crime being either violent or property and “separate” does not; (b) “high” murder cost accounts for value of a statistical life, while “low” does not; (c) Source: National Center for Education Statistics (Various) for 1975-1982 (annually); (d) Based on Michigan “per-pupil expenditures” (special education costs calculated using (National Center for Education Statistics, Various, 1975-1982, annually)); (e) Based on expenditure per full-time-equivalent student (from National Center for Education Statistics (1991)); (f) Based on regular high school costs and estimates from Tsang (1997); (g) Treatment minus control; (h) Includes all kinds of cash assistance and in-kind transfers.

### 3.3. Program Benefits: Employment and Earnings

To construct lifetime earnings profiles, we must solve two practical problems. First, job histories were constructed retrospectively only for a fixed number of previous job spells.<sup>25</sup> Missing data must be imputed using econometric techniques. Second, the Perry set end at the time of the “age-40” interview. In order to generate lifetime profiles, it is necessary to predict earnings profiles beyond this age or else to estimate rates of return through age 40. The latter assumption is conservative in assuming no persistence of treatment effects past age 40. We report both sets of estimates in this paper. The proportion of non-missing earnings data is about only 70 percent for ages 19–40. Web Appendix G presents descriptive statistics and the procedures used to extrapolate earnings when extrapolation is used.

*Imputation.* To impute missing values for periods prior to the age-40 interview, we use four different imputation procedures. First, we use simple piece-wise linear interpolation, based on weighted averages of the nearest observed data points around a missing value. This approach is used by

---

<sup>25</sup>At each interview, participants were asked to provide information about their employment history and earnings at each job for several previous jobs. From this interview design, three problems arise. First, for people with high job mobility, some past jobs are unreported. Second, for people who were interviewed in the middle of a job spell, it may not be possible to precisely specify the end point of that job spell — that is, we have a “right-censoring” problem for the job spells at the time of interview. Third, even when the dates for each job spell can be precisely specified, it is not possible to identify how earning profiles evolve within each job spell because an interviewee reports only one earnings value for each job.

Belfield, Nores, Barnett, and Schweinhart (2006). For truncated spells,<sup>26</sup> we first impute missing employment status with the mean of the corresponding gender-treatment data from the available sample at the relevant time period, and then we interpolate. Second, we impute missing values using estimated earnings functions fit on the 1979 National Longitudinal Survey of Youth (NLSY79) “low-ability”<sup>27</sup> African-American subsample whose life spans overlap with Perry subjects. Heckman, Moon, Pinto, Savelyev, and Yavitz (2009) show that this subset of the NLSY79 is similar in characteristics and outcomes to the Perry controls. We estimate earnings functions for each NLSY79 gender-age cross-section using education dummies, work experience and its square as regressors and then impute from this equation the missing values for the corresponding Perry gender-age cross-section. For truncated spells, we assume symmetry around the truncation points. Third, we use a kernel matching method that matches each Perry subject to similar observations in NLSY79 sample so that we can use the NLSY79 to impute missing values in Perry. Each Perry subject is matched to all observations in the NLSY79 comparison group sample, but with different weights which

---

<sup>26</sup>As noted in the previous footnote, there are job spells in progress at the time of interview.

<sup>27</sup>This “low-ability” subsample is selected by initial background characteristics that mimic the eligibility rule actually used in the Perry program. NLSY79 is a nationally-representative longitudinal survey whose respondents are almost at the same age (birth years 1956–1964) as the Perry sample (birth years 1957–1962). We extract a comparison group from this data using birth order, socioeconomic status (SES) index, and AFQT test score. These restrictions are chosen to mimic the program eligibility criteria of the Perry study. For details, see Web Appendix F.

depend on the Mahalanobis distance measure (Mahalanobis, 1936). For truncated spells, we first match the length of spells, and then earnings. Fourth, we estimate dynamic earnings functions using the method of Hause (1980), discussed by MaCurdy (2007), for each NLSY79 age-gender group. This procedure decomposes individual earnings processes into observed abilities, unobserved heteroscedasticity and serially correlated shocks. The procedure uses the estimated parameters of the Hause model to impute missing values in the Perry earnings data. For truncated spells, we assume symmetry around truncation points. All four methods are conservative in that they impose the same earnings structure on the missing data for treatment and controls. The fourth method preserves differences in pre-existing patterns of unobservables between treatments and controls. See Appendix G for further discussion.

*Extrapolation.* Given the absence of earnings data after age 40, we employ three extrapolation schemes to extend sample earnings profiles to later ages. First, we use 2002 March Current Population Survey (CPS) data to obtain earnings growth rates up to age 65. Since the CPS does not contain measures of cognitive ability, it is not possible to extract “low ability” subsamples from the CPS that are comparable to the Perry control group. We use CPS age-by-age growth rates (rather than levels of earnings) of three-year moving average of earnings by race, gender, and educational attainment to

extrapolate earnings, thereby avoiding systematic selection effects in levels.<sup>28</sup> We link the CPS changes to the final Perry earnings. Second, we use the Panel Study of Income Dynamics (PSID) to extrapolate earnings profiles past age-40. In the PSID, there is a word-completion test score from which we can extract a “low ability” subsample in a fashion similar to the way we extract a matched sample from the NLSY79 using AFQT scores.<sup>29</sup> To extrapolate Perry earnings profiles, we first estimate a random effects model of earnings using lagged earnings, education dummies, age dummies and a constant as regressors. We use the fitted model to extrapolate earnings after age 40.<sup>30</sup> Third, we also use individual parameters from an estimated Hause (1980) model. For computing rates of return, we obtain complete lifetime earnings profiles from these procedures and compare the results of using alternative approaches to extrapolation on estimated rates of return.<sup>31</sup>

All three methods are conservative in that they impose the same earnings dynamics on treatments and controls. However, in making projections all three account for age-40 individual earnings differences between treatments

---

<sup>28</sup>Belfield et al. (2006) use mean values of CPS earnings in their Perry extrapolations. In doing so, they ignore the points that Perry subjects belong to the bottom of the distribution of ability and that CPS subjects are sampled from a more general population with higher average ability.

<sup>29</sup>For information on how we extract this subsample from PSID, see Web Appendix F.

<sup>30</sup>By taking residuals from a regression of earnings on a constant, period dummies and birth year dummies, we can remove fluctuations in earnings due to period-specific and cohort-specific shocks. See Rodgers et al. (1996) for a description of the procedure we use.

<sup>31</sup>For all profiles used here, survival rates by age, gender and education also are incorporated, which are obtained from National Vital Statistics Reports (2004). Belfield et al. (2006) do not account for negative correlation between educational attainment and death rates.

and controls.

The earnings presented in Web Appendix G, Tables G.4 and G.5, include all types of fringe benefits listed in Employer Costs for Employee Compensation (ECEC), a Bureau of Labor Statistics (BLS) compensation measure. Even though the share of fringe benefits in total employee compensation varies across industries, due to data limitations, our calculations assume the share to be constant at its economy-wide average regardless of industry given the data limitations.<sup>32</sup>

### *3.3.1. Preferred Specification for Interpolation and Extrapolation*

Our preferred method of interpolation uses the matched NLSY79 data in a kernel matching procedure. This approach imposes the fewest functional form assumptions on the earnings equations and is more data-sensitive than crude interpolation schemes. Our preferred method of extrapolation uses the matched PSID data. An autoregressive earnings function with freely specified covariates is the least functionally form dependent. At the same time it enables us to link post-age-40 earnings with the observed earnings at 40 and respects differences in unobservables between treatments and controls. We establish below that our estimates are robust to the choice of alternative extrapolation/interpolation procedures.

---

<sup>32</sup>The share of fringe benefit has fluctuated over time with the historical average of about 30 percent. We apply the economy-wide average share at the corresponding year to each person's earnings assuming all fringe benefits tax-free given data limitation.

### *3.4. Program Benefits: Criminal Activity*

Crime reduction is a major benefit of the Perry program (see, for example, Schweinhart et al., 2005, and Heckman et al., 2009). For each subject, the Perry data provide a full record of arrests, convictions, charges and incarcerations for the years 1981–2002 obtained from administrative data sources.<sup>33</sup> The empirical challenges addressed in this section are twofold: obtaining a complete lifetime profile of criminal activities for each person, and assigning value to the impact of that criminal activity. Web Appendix H presents a comprehensive analysis of the crime data summarized in the main text of this paper.

#### *3.4.1. Lifetime Crime Profiles*

Even though the arrest records for Perry cover most of adolescence and adult life, information about criminal activities stops around the time of the age-40 interview.<sup>34</sup> To overcome this difficulty, we use national crime statistics published in the Uniform Crime Report (UCR), which are collected by the Federal Bureau of Investigation (FBI) from state and local agencies nationwide. The UCR provides arrest rates by gender, race, and age for

---

<sup>33</sup>There are some limitations. At the county (Washtenaw) level, arrests, convictions, incarceration, case numbers, and status are reported. At the state (Michigan) level, arrests are only reported when they lead to convictions. For the 38 Perry subjects spread across the 19 states other than Michigan at the time of the age-40 interview, only 11 states provided criminal records. No corresponding data are provided for subjects residing abroad.

<sup>34</sup>The youngest subject's record covers ages 8–39 and that of the oldest covers ages 13–44.

each year. We apply population rates to estimate missing crime.<sup>35</sup> See the discussion in Web Appendix H.

### 3.4.2. *Crime Incidence*

Estimating the impact of the program on crime requires estimating the true level of criminal activity at each age and obtaining reasonable estimates of the social cost of each crime. For a crime of type  $c$  at time  $t$ , the total social cost of that crime  $V_t^c$  can be calculated as a product of the social cost per unit of crime  $C_t^c$  and the incidence  $I_t^c$ :

$$V_t^c = C_t^c \times I_t^c.$$

We do not directly observe the true incidence level  $I_t^c$ . Instead, we only observe each subject's arrest record at age  $t$  for crime  $c$ ,  $A_t^c$ . If we know the incidence-to-arrest ratio  $I_t^c/A_t^c$  from other data sources, we can estimate  $V_t^c$  by multiplying the three terms in the following expression:

$$V_t^c = C_t^c \times \frac{I_t^c}{A_t^c} \times A_t^c.$$

To obtain the incidence-to-arrest ratio  $I_t^c/A_t^c$  for each crime of type  $c$  at time  $t$ , we use two national crime datasets: the Uniform Crime Report (UCR) and the National Crime Victimization Survey (NCVS).<sup>36</sup> The UCR

---

<sup>35</sup>We use the year-2002 UCR for this extrapolation.

<sup>36</sup>The Federal Bureau of Investigation website provides annual reports based on UCR (<http://www.fbi.gov/ucr/ucr.htm>). NCVS are available at Department of Justice web-

provides comprehensive annual arrest data between 1977 and 2004 for state and local agencies across the U.S. The NCVS is a nationally-representative household-level data set on criminal victimization which provides information on unreported crime levels across the U.S. By combining these two sources, we can calculate the incidence-to-arrest ratio for each crime of type  $c$  at time  $t$ . As noted in the UCR (2002), however, the crime typologies derived from the UCR and those of the NCVS are “not strictly comparable.” To overcome this problem, we developed a unified categorization of crimes across the NCVS, UCR, and Perry data sets for felonies (Web Appendix H, Table H.4) and misdemeanors (Web Appendix H, Table H.5). Web Appendix H, Table H.7, shows our estimated incidence-to-arrest ratios for these crimes. To check the sensitivity of our results to the choice of a particular crime categorization, we use two sets of incidence-to-arrest ratios and compare results. For the first set, we assume that each crime type has a different incidence-to-arrest ratio. These are denoted “Separated” in our tables. For the second set, we use two broad categories, violent vs. property crime. These are denoted by “Property vs. Violent” in our tables. Further, to account for local context, we calculate ratios using UCR/NCVS crime levels that are geographically specific to the Perry program: only crimes committed or arrests made in Metropolitan Sampling Areas of the Midwest.<sup>37</sup>

---

site (<http://www.ojp.usdoj.gov/bjs/cvict.htm>).

<sup>37</sup>For this purpose, the Midwest is defined as Ohio, Michigan, Indiana, Illinois, Wisconsin, Minnesota, Iowa, Missouri, North Dakota, South Dakota, Nebraska, and Kansas. The City of Ypsilanti, where the Perry Preschool Program was conducted, belongs to the

### 3.4.3. Unit Costs of Crime

Using a simplified version of a decomposition developed in Anderson (1999) and Cohen (2005), we divide crime costs into victim costs and Criminal Justice System costs, which consist of police, court, and correctional costs.

*Victim Costs.* To obtain total costs from victimization levels, we use unit costs from Cohen (2005). Different types of crime are associated with different victimization unit costs. Some crimes are not associated with any victimization costs. In Web Appendix H, Table H.13, we summarize the unit cost estimates used for different types of crime.

*Police and Court Costs.* Police, court, and other administrative costs are based on Michigan-specific cost estimates per arrest calculated from the UCR and Expenditure and Employment Data for the Criminal Justice System (CJEE) micro datasets.<sup>38</sup> Since we only observe arrests, and do not know whether and to what extent the courts were involved (for example, whether there was a trial ending in acquittal), we assume that each arrest incurred

---

Detroit Metropolitan Sampling Area. For a comparison of these ratios between the local and national levels, see Web Appendix H.3.

<sup>38</sup>From Bureau of Justice Statistics (2003), we obtain total expenditures on police and judicial-legal activities by federal, state, and local governments. We divide the expenditures from Michigan state and local governments by the total arrests in this area obtained from UCR. To account for federal agencies' involvement, we add another per-arrest police/court cost which is calculated by dividing the total expenditure of federal government with the total arrests at national level. This calculation is done for years 1982, 1987, 1992, 1997, and 2002. For periods between selected years, we use interpolated values. See Web Appendix H.

an average level of all possible police and court costs. This unit cost was applied to all observed arrests (regardless of crime type).

*Correctional Costs.* Estimating correctional costs in Perry is a more straightforward task, as the data include a full record of incarceration and parole/probation for each subject. To estimate the unit cost of incarceration, we use expenditures on correctional institutions by Michigan state and local governments divided by the total institution population. To estimate the unit cost of parole/probation, we perform a similar calculation.<sup>39</sup>

#### 3.4.4. *Estimated Social Costs of Crime*

Table 2 summarizes our estimated social costs of crime. Our approach differs from that used by Belfield et al. (2006) in several respects. First, in estimating victimization-to-arrest ratios, police and court costs, and correctional costs, we use local data rather than national figures. Second, we use two different values of the victim cost of murder: an estimate of “the statistical value of life” (\$4.1 million) and an estimate of assault victim cost (\$13,000).<sup>40</sup> We report separate rates of return for each estimate. Only four

---

<sup>39</sup>Belfield et al. (2006) compute crime-specific criminal-justice system costs. Even though in principle this approach could be more accurate than ours, we do not adopt it in this paper because their data source is questionable and we could not find any other relevant sources. Their unit cost estimates are obtained from a study of the police and courts of Dade County, Florida which has quite different characteristics from Washtenaw County, Michigan where the Perry experiment was conducted. We examine the sensitivity of our estimates to alternate ways to measure costs in Table 4. See Web Appendix H for further discussion.

<sup>40</sup>See Cohen (2005) and, for a literature review, see Viscusi and Aldy (2003), who provides a range of \$2-9 million for the value of a statistical life.

murders are observed in the Perry arrest records.<sup>41</sup> If one uses the statistical value of life as the cost of murder to the victim, a single murder might dominate calculation of the rate of return. To avoid this problem, Barnett (1996) and Belfield et al. (2006) assign murder the same low cost as assault. We adopt this as one approach for valuing the social cost of murder, but we also explore an alternative that includes the statistical value of life in murder victimization costs. Contrary to intuition, however, assuming a lower murder cost is not “conservative” in terms of estimating rate of return because the lone treated male murderer committed his crime at a very early age (21) while the two control male murderers committed their crimes in their late 30s. As a result, assigning a high victimization cost to murder decreases the rate of return for males. Given the temporal pattern of murder, we present rate-of-return estimates using both “high” and “low” victim costs for murder (the former including the statistical value of life, and the latter not) and compare the results. Third, we assume that there are no victim costs associated with “driving misdemeanors” and “drug-related crimes”. Whereas previous studies have assigned non-trivial victim costs to these types of crimes, we consider them to be “victimless”. Although such crimes could be the proximal cause of victimizations, these victimizations would be directly associated with other crimes for which we already explicitly account.<sup>42</sup> This approach

---

<sup>41</sup>One is committed by a control female, two by control males, and one by a treated male.

<sup>42</sup>“Driving misdemeanors” include driving without a license; suspended license; driving under the influence of alcohol or drugs; other driving misdemeanors; failure to stop at

results in a substantial decrease of crime cost compared to the cost of crime used in previous studies because these specific crimes account for more than 30 percent of all crime reported in the Perry study.

### *3.5. Tax Payments*

Taxes are transfers from the taxpayer to the rest of society. They benefit recipients and reduce the welfare of the taxed unless services are received in return. Our analysis considers benefits to recipients, benefits to the public, and total social benefits (or costs). The latter category nets out transfers but counts costs of collecting and avoiding taxes.

Higher earnings translate into higher absolute amounts of income tax payments (and consumption tax payments) that are beneficial to the general public excluding program participants. Since U.S. individual income tax rates and the corresponding brackets have changed over time, in principle we should apply relevant tax rates according to period, income bracket, and filing status. In addition, most wage earners must pay the employee's share of the Federal Insurance Contribution Act (FICA) tax, such as the Social Security tax and the Medicare tax. In 1978, employee's marginal and average FICA tax rate for a four-person family at a half of US median income was

---

accident; improper license plate. "Drug-related crimes" include drug abuse, sale, possession, or trafficking. Belfield et al. (2006) use \$3,538 to evaluate the cost of "driving misdemeanors" and \$2,620 for "drug-related crimes" (in year-2006 dollars). Rolnick and Grunewald (2003) do not document how they treat crime. Belfield et al. (2006) compute expected victim costs for these cases, which include, for example, probable risk of death. This practice leads to double counting, and thus to overstating savings in victimization costs.

6.05 percent of taxable earnings. It gradually increased over time, reaching 7.65 percent in 1990, and has remained at that level ever since.<sup>43</sup> Here, we simplify the calculation by applying a 15 percent individual tax rate and 7.5 percent FICA tax rate to each subject’s taxable earnings in each year.<sup>44</sup> Belfield, Nores, Barnett, and Schweinhart (2006) use the employer’s share of FICA tax in addition to these two components in computing the benefit to the general public, but we do not. A recent consensus among economists is that “employer’s share of payroll taxes is passed on to employees in the form of lower wages than would otherwise be paid.”<sup>45</sup> Since this tax burden is already incorporated in realized earnings, we do not count it in computing the benefit accrued to the general public while employers who are also among the general public pay some money to the government. Web Appendix J, Tables J.1–J.3, show how individual gross earnings are decomposed into net earnings and tax payments under this assumption.

### *3.6. Use of the Welfare System*

Most Perry subjects were significantly disadvantaged and received considerable amounts of financial and non-financial assistance from various welfare

---

<sup>43</sup>See Tax Policy Center (2007).

<sup>44</sup>The “effective” tax rate for the working poor is much higher than this because people lose eligibility for various welfare programs or withdraw benefits as income increases. See Moffitt (2003). Because, in computing the rate of return, we account for the effects of Perry on all kinds of welfare benefits, including in-kind transfers we apply these baseline tax rates to earnings data alone to avoid double-counting.

<sup>45</sup>Congressional Budget Office (2007). Anderson and Meyer (2000) present empirical evidence supporting this view.

programs. Differentials in the use of welfare are another important source of benefit from the Perry Program. We distinguish transfers, which may benefit one group in the society at the expense of another, from the costs associated with making such transfers. Only the latter should be counted in computing gains to society as a whole.

We have two types of information on the use of the welfare system: incidence of welfare dependence, and actual welfare payments. Web Appendix I, Table I.1, presents descriptive statistics comparing welfare incidence, the length of welfare spells, and the amount of welfare benefits that are actually received by treatments and controls. One finding is that control females depend on welfare programs more heavily than treatment females before age 27. That pattern is reversed at later ages.<sup>46</sup> For males, the scale of welfare usage is lower, with controls more likely to use welfare at all ages.

Two types of data limitations affect our calculation. One is that we do not have enough information about receipt of various in-kind transfer programs,

---

<sup>46</sup>Belfield et al. (2006) suggest that “delayed child-rearing and higher education attainment” among treatment females can explain this phenomenon. However, this pattern is at odds with evidence from the NLSY79 in which greater use of welfare is associated with lower educational attainment. Bertrand, Luttmer, and Mullainathan (2000) show that a person’s welfare participation can be affected by behaviors of others in a network. Since the program was conducted in a small town (Ypsilanti, Michigan) and the treated females have known each other from their childhood, they could presumably share and exchange information about welfare programs. This may have made it easier for them to apply and receive benefits. In the NLSY79 which samples randomly from many communities, this effect is unlikely to be at work. If the network effect was dominant, the observed contradictory pattern should be interpreted as the composite of treatment effect and network effect. While having a better social network also could be a treatment effect, this distinction would be useful for investigating the external validity of this program.

such as medical, housing, education, and energy assistance, which represent a large portion of total U.S. welfare expenditures. The other is that even for cash assistance programs such as General Assistance (GA), AFDC/TANF, and Unemployment Insurance (UI), we do not have complete lifetime profiles of cash transfers for each individual. Given these limitations, we adopt the following method to estimate full lifetime profiles of welfare receipt.

First, we use the NLSY79 and PSID comparison samples to impute the amount received from various cash assistance and food stamp programs. Prior to age 27, we employ the NLSY79 black “low ability” subsample. Since only the total number of months on welfare programs is known for the Perry sample during this age range, such imputations are unavoidable. We impute individual monthly welfare receipt for each year using coefficients from NLSY79 individual receipts for the corresponding year regressed on gender and education indicators, a dummy variable for teenage pregnancy, number of months in wedlock, employment status, earnings, and the number of biological children.<sup>47</sup> In this regression, welfare receipts include food stamps and all kinds of cash assistance available in the NLSY79 dataset, such as Unemployment Insurance (UI), AFDC/TANF, Social Security, Supplemental Security Income (SSI), and any other cash assistance. For ages 28–40, the Perry records provide both the total number of months on welfare and the cumulative amount of receipts through UI, AFDC, and food stamps. We

---

<sup>47</sup>The exact imputation equation is given in Web Appendix I.

use the observed amounts for these programs. For other welfare programs, we use a regression-based imputation scheme similar to that used prior to age 27. The total amount is computed as a sum of these two components. To extrapolate this profile past age 40, we use the PSID dataset, which contains profiles over longer stretches of the life cycle than does the NLSY79. As with the earnings extrapolation, we target the “low-ability” subsample of the PSID dataset. We first estimate a random effects model of welfare receipt using a lagged dependent variable, education dummies, age dummies, and a constant as regressors. We use the fitted model to extrapolate. As with the NLSY79 imputation, the dependent variable in this model includes all cash assistance and food stamps.<sup>48</sup>

Second, to account for in-kind transfers, we employ the Survey of Income and Program Participation (SIPP) data. In SIPP, we calculate the probability of being in specific in-kind transfer programs for a “less-educated” black population born between the years 1956 and 1965, using the year-1984, -1996, and -2004 micro datasets.<sup>49</sup> We estimate linear probability models for participation in each of a variety of programs using gender and educational attainment variables as predictors.<sup>50</sup> This calculation is done separately for Medicaid, Medicare, housing assistance, education assistance, energy assis-

---

<sup>48</sup>We remove cohort and year effects in a fashion similar to what is done for earnings extrapolation. See Web Appendices G and I.

<sup>49</sup>Since SIPP does not contain any kind of ability measure, we use a subsample whose educational attainment is less than or equal to “some college credits without diploma.”

<sup>50</sup>We fit the same equation to both treatment and control group members.

tance, public training programs, and other public service programs. We use interpolated values for periods between the years of the respective micro datasets. Past 2004, we use year-2004 estimates assuming that the current welfare system continues. To convert this probability to monetary values, we use the estimates of Moffitt (2003) for real expenditures on the combined federal, state, and local spending for the largest 84 means-tested transfer programs. We adjust upward cash assistance amounts by a product of the probability of participation in each program and the ratio of real expenditures of the in-kind program to that of cash assistance, so that the resulting amount becomes the expected cash value of in-kind receipt. We aggregate across programs to obtain overall totals. Table 2 summarizes our estimated profiles of welfare use.

For society, each dollar of welfare involves administrative costs. Based on Michigan state data, Belfield, Nores, Barnett, and Schweinhart (2006) estimate a cost to society of 38 cents for every dollar of welfare disbursed. We use this estimate to calculate the cost of welfare programs to society.<sup>51</sup>

### *3.7. Other Program Benefits*

Other possibly beneficial effects of the Perry program that cannot be easily quantified include the psychic cost of education, the utility gain from committing crime, the value of leisure, the value of marital and parental out-

---

<sup>51</sup>This cost consists of two components: the cost of administering welfare disbursement and the cost accrued to overpayments and payments to ineligible families.

comes, the contribution of the program to child care, the value of wealth accumulation, the value of social life, the value of improved health and longevity, and any intergenerational effects of the program.<sup>52</sup> These benefits are not included in our analysis due to data limitations.

#### 4. Internal Rates of Return and Benefit-To-Cost Ratios

In this section, we calculate internal rates of return and benefit-cost ratios for the Perry Preschool Program under various assumptions and estimation methods. The internal rate of return (IRR) compares alternative investment projects in a common metric. For each gender and treatment group, we construct average life cycle benefit and cost profiles and then compute IRRs. We also compute standard errors for all of the estimated IRRs and benefit-cost ratios. The computation of standard errors is constructed in three steps. In the first step, we use the bootstrap to simultaneously draw samples from Perry, the NLSY79, and the PSID.<sup>53</sup> For each replication, we re-estimate all parameters that are used to impute missing values, and re-compute all components used in the construction of lifetime profiles. Notice

---

<sup>52</sup>In this study, we do not include the child care cost that parents of program subjects would have paid without this program to narrow our scope to the benefits of the current generation. Thus, we likely underestimate the true benefits. The effect on longevity is accounted for to some degree because we adjust all profiles used in this study for survival rates by age, gender and educational attainments. Belfield, Nores, Barnett, and Schweinhart (2006) count child care for participants as a benefit, even for women who do not work, and hence they inflate the benefits of the Perry Program.

<sup>53</sup>For procedures that use different nonexperimental samples, we conduct the same analysis.

that in this process, all components whose computations do not depend on the comparison group data also are re-computed (e.g., social cost of crime, educational expenditure, etc.) because the replicated sample consists of randomly drawn Perry participants. In the second step, we adjust all imputed values for prediction errors on the bootstrapped sample by plugging in an error term which is randomly drawn from comparison group data by a Monte Carlo resampling procedure. Combining these two steps allows us to account for both estimation errors and prediction errors. Finally we compute point estimates of IRRs for each replication to obtain bootstrap standard errors. Web Appendix K describes the procedure used to compute standard errors in greater detail.

Table 1, Table 3, and Web Appendix J show estimated IRR's computed using various methods for estimating earnings profiles and crime costs and under various assumptions about the deadweight cost of taxation. Numbers in parentheses below each estimate are the associated standard errors. We first use the victim cost associated with a murder as \$4.1 million, which includes the statistical value of life (Column labeled "High"). We also provide calculations setting the victim cost of murder to that of assault, which is about \$13,000, to avoid the problem that a single murder might dominate the evaluation (final two sets of columns). To gauge the sensitivity of estimated returns to the way crimes are categorized, we first assume that crimes are separated and compute victimization ratios separately for each crime (columns labeled "Separated"). We then aggregate crimes into two

Table 3: Internal Rates of Return (%), by Imputation and Extrapolation Method and Assumptions About Crime Costs Assuming 50% Deadweight Cost of Taxation

Victimization/Arrest Ratio <sup>a</sup>	Returns:		To Society, Including the Individual (Nets out Transfers)												
	To Individual		Separated				Separated				Property vs. Violent				
	All <sup>c</sup>	Female	All <sup>c</sup>	Male	Female	All <sup>c</sup>	Male	Female	All <sup>c</sup>	Male	Female	All <sup>c</sup>	Male	Female

**Notes:** Standard errors in parentheses are calculated by Monte Carlo resampling of prediction errors and bootstrapping. All estimates are adjusted for compromised randomization. All available local data and the full sample are used unless otherwise noted. (a) A ratio of victimization rate (from the NCVS) to arrest rate (from the UCR), where “Property vs. Violent” uses common ratios based on a crime being either violent or property and “separate” does not; (b) “high” murder cost valuation accounts for statistical value of life, while “low” does not; (c) The “all” IRR represents an average of the profiles of a pooled sample of males and females, and may be lower or higher than the profiles for each gender group; (d) Piecewise linear interpolation between each pair reported; (e) Cross-sectional regression imputation using a cross-sectional earnings estimation from the NLSY79 black low-ability subsample. (f) Kernel-matching imputation matches each Perry subject to the NLSY79 sample based on earnings, job spell durations, and background variables; (g) Based on the Hause (1980) earnings model

categories: property and violent crimes, and compute victimization ratios within each category. Average costs of crime are computed for each category. The estimates reported in these tables account for the deadweight costs of taxation: dollars of welfare loss per tax dollar. Since different studies suggest various estimates of the size of the deadweight cost of taxation, in this paper we show the results for various assumptions for the size of deadweight loss associated with \$1 of taxation: 0, 50, and 100 percent.<sup>54</sup> There are many components of the calculation that are affected by this consideration: initial program cost, school expenditure paid by the general public, welfare receipt and the overhead cost of welfare paid by the general public, and all kinds of criminal justice system costs such as police, court, and correctional costs.<sup>55</sup> The Perry Program incurs the deadweight costs associated with initial funding but saves the deadweight costs associated with taxes used to fund transfer recipients. Table 1 provides a comparison of results across different assumptions of the deadweight costs for the selected earnings imputation and extrapolation method, and Table 3 presents results across different earnings imputation and extrapolation methods under 50 % of the deadweight cost which we prefer. A complete set of our results can be found in Web Appendix J.<sup>56</sup>

---

<sup>54</sup>See Browning (1987), Heckman and Smith (1998), Heckman et al. (1999), and Feldstein (1999) for discussion of estimates of deadweight costs.

<sup>55</sup>We do not apply this adjustment to income tax paid by Perry subjects to avoid double counting. Observed earnings are already adjusted for taxes. See the discussion in Web Appendix J.

<sup>56</sup>In principle, since different types of taxes are levied by different jurisdictions that

Table 1 compares estimates with and without adjustment for compromised randomization. Heckman, Moon, Pinto, Savelyev, and Yavitz (2009) document that the randomization protocol implemented in the Perry Preschool Program is somewhat problematic.<sup>57</sup> Post-randomization reassignments were made to promote compliance with the program. This and other modifications to simple random assignment created an imbalance between treatment and control group in family background such as father’s presence at home, Socio-Economic Status (SES) index, and mother’s employment status at program entry.<sup>58</sup> This imbalance could induce a spurious relationship between outcomes and treatment assignments, which violates the assumption of inde-

---

create different deadweight losses, we should account for this feature of the welfare system. In practice, this is not possible. Web Appendix J, Tables J.1–J.3, take the reader through the calculation underlying three of the cases reported in this table.

<sup>57</sup>The randomization protocol used in the Perry Preschool Program was complex. For each designated eligible entry cohort, children were assigned to treatment and control groups in the following way. (1) Participant status of the younger siblings is the same as that of their older siblings; (2) Those remaining were ranked by their entry IQ score with odd- and even-ranked subjects assigned to separate groups; (3) Some individuals initially assigned to one group were swapped between groups to balance gender and mean SES scores, “with Stanford-Binet scores held more or less constant”. This produced an imbalance in family background variables; (4) A coin toss randomly selected one group as the treatment group and the other as the control group; (5) Some individuals provisionally assigned to treatment, whose mothers were employed at the time of the assignment, were swapped with control individuals whose mothers were not employed. The rationale for this swap was that it was difficult for working mothers to participate in home visits assigned to the treatment group. For details on the randomization protocol, see Weikart et al. (1978) and Heckman, Moon, Pinto, Savelyev, and Yavitz (2009). The latter paper analyzes program treatment effects accounting for the corrupted randomization.

<sup>58</sup>The fraction of children with working mothers at study entry is much higher in the control group (31%) than in the treatment group (9%). This trend continues to hold when males and females are viewed separately. In contrast, treatment females had a greater fraction of fathers present at study entry than control females (68% vs. 42%), while treatment males had a smaller fraction of fathers present than control males (45% vs. 56%).

pendence that is the core concept of a randomized experiment. To produce valid IRRs and standard errors, researchers should take into account the corruption of the randomization protocol used to evaluate the Perry program and to examine its effects on estimated rates of return. One way to control for potential biases is to condition all lifetime cost and benefit streams on the variables that determine reassignment. By adjusting cost and benefit streams for these variables, corruption-adjusted IRRs and the associated standard errors can be computed.<sup>59</sup> As Table 1 shows, however, adjustment does not greatly change the estimated IRR, and the effect is not always in the same direction.

The estimated rates of return reported in Table 3 are comparable across different imputation and extrapolation schemes. Kernel matching imputation tends to produce slightly higher estimates. Alternative extrapolation methods have a more modest effect on estimated rates of return.<sup>60</sup> Alternative assumptions about the victim cost of murder — whether to include the statistical value of life — affect the estimated rates of return in a counterintuitive fashion. Assigning a high value to the value of a life *lowers* the estimated rate of return because the one murder committed by a treatment group male occurs earlier than the two committed by males in the control

---

<sup>59</sup>We use the Freedman-Lane procedure discussed in Heckman, Moon, Pinto, Savelyev, and Yavitz (2009). Those authors show that the results from this procedure agree with the results obtained from other parametric and semiparametric estimation procedures.

<sup>60</sup>The profiles labeled as “all” pool the data regardless of gender. The IRR from pooled samples can be higher or lower than the IRR for each separate gender subsample.

group.<sup>61</sup> Although estimated costs are sensitive to assumptions about the victimization cost associated with murder, they are not very sensitive to the crime categorization method. Adjusting for deadweight losses of taxes lowers the rate of return to the program. Our estimates of the overall rate of return hover in the range of 7–10 percent. They are statistically significantly different from zero in most cases.<sup>62</sup>

Table 4 demonstrates how IRRs change when we exclude outliers from our computation. We consider two types of outliers: subjects who attain more than a 4-year college degree and a group of “hard-core” criminal offenders. In the Perry dataset, we observe 2 subjects who acquired master’s degrees: 1 control male and 1 treatment female. Compared to the “full sample” result, excluding these subjects has only modest effects on the estimated IRRs. To exclude the “hard-core” criminals, we use “the total number of lifetime charges” through age 40 including juvenile crimes. We exclude the top 5 percent (six persons) of hard-core offenders from the full sample and recalculate the IRRs.<sup>63</sup> Eliminating these offenders increases the estimated social IRRs obtained from the pooled sample, and strengthens the precision of the estimates.

---

<sup>61</sup>Thus, when Belfield et al. (2006) assign a low value to murder victimization, they are actually presenting an upward-biased estimate.

<sup>62</sup>Tables J.4 and J.5 in Web Appendix J present the estimates for other assumptions about deadweight loss.

<sup>63</sup>Web Appendix H, Table H.12, identifies these individuals. This group consists of 3 control males and 3 treatment males. This small group commits about 25 percent of all charges and 27 percent of all felony charges associated with non-zero victim cost.

Table 4: Sensitivity Analysis of Internal Rates of Return (%)

**Notes:** All estimates reported are adjusted for compromised randomization. Kernel matching imputation and PSID projection are used for missing earnings. Standard errors in parentheses are calculated by Monte Carlo resampling of prediction errors and bootstrapping. Deadweight cost of taxation is assumed at 50 percent. All available local data and the full sample are used unless otherwise noted. (a) A ratio of victimization rate (from the NCVS) to arrest rate (from the UCR), where “Property vs. Violent” uses common ratios based on a crime being either violent or property and “separate” does not; (b) “High” murder cost accounts for statistical value of life, while “low” does not; (c) “All” is computed from an average of the profiles of the pooled sample, and may be lower or higher than the profiles for each gender group; (d) Excluding 2 subjects with masters degrees (1 control male and 1 treatment female); (e) Excluding the top 5 percent of hard-core recidivists (3 control males and 3 treatment males); (f) National means are used in all computations. All national figures are obtained from the same source of local data; (g) Based on Crime-Specific CJS Costs from Belfield et al. (2006).

Table 4 also compares our estimates with two other sets of IRRs: one based on national figures in all computations and the other on crime-specific criminal justice system (CJS) costs used in Belfield et al. (2006). Accounting for local costs instead of relying on national figures increases estimated IRRs. The signs and magnitude of the effect of using local costs differs by cost component. As noted in Section 3, schooling expenditures for K-12 education in Michigan are slightly higher than the corresponding figures at the national level, although accounting for this has only modest effects on the estimated IRRs. The modest effect arises because total education expenditure is not substantially different between the control and the treatment group after accounting for grade retention, special education, and years in regular schooling. Using local crime costs increases the estimated IRR and increases the precision of the estimates. No clear pattern emerges from using local versus national victimization-to-arrest ratios. However, criminal justice system costs for Michigan are unambiguously higher than the corresponding national means and accounting for these raises the estimated rate of return. Using the crime-specific CJS costs employed by Belfield et al. (2006) has mixed effects on the estimated IRR depending on the victimization-to-arrest ratio used. As noted in Section 3, their estimated costs of the criminal justice system are based on data collected from a specific local area whose characteristics are quite different from the region where the Perry Preschool Program was conducted.

#### 4.1. Benefit-To-Cost Ratios

As noted in Hirshleifer (1970), use of the IRR to evaluate programs is potentially problematic.<sup>64</sup> For this reason, it is useful to consider benefit-to-cost ratios using different discount rates. Table 1 and Tables J.6–J.9 in Appendix J present the benefit-to-cost ratios and the associated standard errors. Tables J.6–J.9 show that ratios adjusting for compromised randomization. For typical discount rates (3–5 percent), we estimate substantial benefit-to-cost ratios.<sup>65</sup> The benefit-to-cost ratios generally support the rate of return analysis.

#### 4.2. Age 40 Analysis

Table 5 presents a more conservative version of our preferred analysis (kernel matching for imputation and PSID extrapolation with a 50% dead-weight loss). Instead of computing the rate of return and benefit-cost ratios through age 65, we compute rate of return and benefit-cost analysis only

---

<sup>64</sup>The internal rate of return is the solution  $\rho$  of a polynomial equation  $\sum_{t=1}^T \frac{Y_t^{Tr} - Y_t^{Ctl}}{(1+\rho)^t} - \bar{C} = 0$ , where  $Y_t^{Tr}$  and  $Y_t^{Ctl}$  denote lifetime net benefit streams at time  $t$  for treatment and control group, respectively, and  $\bar{C}$  is the initial program cost. Given the high order of this equation ( $T=65-3=62$ ), there may be multiple real solutions and some solutions may be complex. Fortunately, however, a unique positive real solution  $\rho^*$  is found for *all* of the combination of methodologies and assumptions examined in this paper. While we obtain a unique positive real IRR, it is still problematic whether IRR or Benefit-to-Cost ratio can serve as a “correct” criterion for a policy decision comparing two mutually exclusive projects since the project with the higher internal rate of return can have a lower present value than a rival project. See Hirshleifer (1970, p. 76-77). Carneiro and Heckman (2003) discuss the limits of the IRR in the context of evaluating early childhood programs.

<sup>65</sup>The appropriate social discount rate is a hotly debated topic. Some have argued for a zero or negative social discount rate (Dasgupta, Mäler, and Barrett, 2000).

through age 40, assuming that benefits stop after that age. This eliminates the need to extrapolate past age 40, and so eliminates one source of model uncertainty. We compare the estimates from the third row of Table 3 with the estimates that assume that benefits stop at age 40.

Unsurprisingly, rates of return and benefit-cost levels fall somewhat, but in most cases they remain precisely determined. Even under a very conservative assumption, the rate of return is substantial, precisely estimated, and above the historical yield on equity.

#### *4.3. Comparisons with Previous Studies*

Internal rates of return for the Perry Preschool Program have been reported in two previous studies by Rolnick and Grunewald (2003) and Belfield, Nores, Barnett, and Schweinhart (2006). Our estimates of the IRR are lower than those reported in previous studies. While a number of factors produce this effect, the dominant source of the difference between our estimates and the previous estimates is in our treatment of crime and its social costs. In particular, as noted in Section 3, treatment of the social cost of some “victimless” crimes plays a crucial role.

Table 6 compares the estimates reported in previous studies with those reported in this paper. While we employ a variety of methods to estimate lifetime costs and benefits, here we present estimates from only one method, which is similar to the method used in previous studies: linear interpolation and CPS-based extrapolation for missing earnings along with crimes sepa-

**Notes:** Kernel matching is used to impute missing values in earnings before age-40, and PSID projection for extrapolation of later earnings. For details of these procedures, see Section 3. In calculating benefit-to-cost ratios, deadweight loss of taxation is assumed at 50%. Lifetime net benefit streams are adjusted for corrupted randomization by being conditioned on unbalanced pre-program variables. For details, see Section 4. Standard errors in parentheses are calculated by Monte Carlo resampling of prediction errors and bootstrapping; see Web Appendix K for details. (a) The sum of returns to program participants and the general public; (b) “high” murder cost accounts for statistical value of life, while “low” does not; (c) Deadweight cost is dollars of welfare loss per tax dollar; (d) A ratio of victimization rate (from the NCVS) to arrest rate (from the UCR), where “Prop. / Violent” uses common ratios based on a crime being either violent or property and “Separate” does not; (e) “All” is computed from an average of the profiles of the pooled sample, and may be lower or higher than the profiles for each gender group.

rated by type and a low murder cost (\$13,000) assumption. We present two sets of results from our study: one with no deadweight loss, and the other with a 50 percent deadweight loss, which we prefer. Each set is reported adjusting and not adjusting for the compromised randomizations of the program — a feature never previously considered. In addition, no previous study accounts for the deadweight cost of taxation. Compared to the two previous studies, our estimated program benefits are smaller for education and crime, and larger for earnings and welfare costs.

The difference in education cost estimates is mainly caused by our treatment of vocational training. As shown in Web Appendix J, Table J.1, the costs of college education and vocational training differ between control and the treatment groups, while the K-12 education costs do not. Previous studies do not account for costs of vocational training.

Our estimated earning differentials are larger for males and smaller for females compared to those reported in previous studies. While our imputation method for missing earnings before age 40 is similar in many respects to the method used in previous studies, our extrapolation method for ages after 40 is different. We account for the fact that Perry subjects are at the bottom of the distribution of ability by using CPS age-by-age growth rates (rather than levels of earnings) to make extrapolations by race, gender and educational attainment. Previous studies neglect this aspect of the Perry sample and use national mean values of CPS earnings to project missing earnings, inflating the level of earnings for both treatments and controls.

Another major difference between our study and previous ones lies in our treatment of the social cost of crime. Our estimated effect of crime reduction is much smaller than that reported in two previous studies. We assume no victim costs are associated with “driving misdemeanors” and “drug-related crimes”. Previous studies assign non-trivial victim costs to these crimes. We consider these crimes as “victimless.” Even though these crimes may be associated with other crimes which may generate victims, they would be recorded as separate crimes in the Perry crime record. This more careful accounting for crime results in a substantial decrease of the estimated cost of crime because victimless crimes account for more than 30 percent of all crime incidence reported in the Perry crime record.

## **5. Conclusion**

This paper estimates the rate of return and the benefit-cost ratio for the Perry Preschool Program, accounting for locally determined costs, missing data, the deadweight costs of taxation, and the value of non-market benefits and costs. It improves on previous estimates by accounting for corruption in the randomization protocol by developing standard errors for these estimates and by exploring the sensitivity of estimates to alternative assumptions about missing data and the value of non-market benefits. Our estimates are robust to a variety of alternative assumptions about interpolation, extrapolation, and deadweight losses. In most cases, they are statistically significantly dif-

Table 6: Comparison with Previous Studies

**Notes:** All monetary values are in year-2006 dollars. Discount rate is assumed at 3 percent. (a) Recalculated from Rolnick and Grunewald (2003, Table 1A), excluding child care cost; (b) Recalculated from Belfield, Nores, Barnett, and Schweinhart (2006, Table 9), excluding child care cost; (c) Linear interpolation and CPS projection are used for missing earnings. Separated crime types and low murder cost (\$13,000) are used for social cost of crime; (d) Unadjusted for compromised randomization; (e) Standard errors are calculated using bootstrapping. They are not computed in Rolnick and Grunewald (2003) or Belfield et al. (2006); (f) Adjusted for compromised randomization.

ferent from zero. This is true for both males and females.<sup>66</sup> In general, the estimated rates of return are well above the historical return to equity of about 5.8 percent but below previous estimates reported in the literature. Table 1 summarizes our estimates of the rate of return. Our benefit-to-cost ratio estimates support the rate of return analysis. Benefits on health and the well-being of future generations are not estimated due to data limitations. All things considered, our analysis likely provides a lower-bound on the true rate of return to the Perry Preschool Program.<sup>67</sup>

<sup>66</sup>A recent paper by Anderson (2008) claims to find no effect for the Perry program for males. He focuses on only a few outcomes and does not compute rates of return or benefit-cost ratios.

<sup>67</sup>Our analysis answers many of the objections raised by Nagin (2001) against previous cost-benefit studies of the returns to early interventions. We consider costs and benefits to society, rather than governments or individuals alone. However, due to data limitations, we do not value the psychic benefits of crime reduction to society at large apart from the reduction in victimization costs.
